A drug reaction can be defined as an undesirable response evoked by a medicinal substance. Any drug is a potential cause of an adverse reaction, although certain classes of drugs can be incriminated more often than others. Major offenders include antibiotics (particularly the newer ones and oral antifungal agents), nonsteroidal anti-inflammatory drugs (NSAIDs), psychotropic agents, β -blockers, calcium channel blockers, thiazides, ACE inhibitors, and gold.¹⁻³ Preservatives and coloring agents in foodstuffs, as well as chemicals used in industry, may sometimes produce cutaneous reactions that are indistinguishable from those produced by medicinal substances. These other agents should always be kept in mind in the etiology of an apparent drug reaction.

Although some drugs cause only one clinical pattern of reaction, most are capable of producing several different types of reaction.⁴ Most of these adverse reactions involve the skin, but organs such as the lungs, kidneys, liver, and lymph nodes may be affected singly or in various combinations.^{5,6} Since the teratogenic effects of thalidomide received widespread coverage approximately 50 years ago, this potential complication receives considerable experimental attention in the early testing of new compounds.^{7,8} Drug fever is another clinical manifestation of an adverse drug reaction.

Continuing advances in pharmacology have resulted in the introduction of an ever increasing number of drugs for therapeutic purposes with a consequent avalanche of case reports detailing adverse reactions.^{9,10} The true prevalence of cutaneous drug reactions is difficult to determine because most studies have been based on hospital inpatients, many of whom are receiving several drugs simultaneously.^{1,11} In these inpatient series, drug reactions have occurred in approximately 2% of patients;¹² this figure is probably not relevant to outpatients. The incidence has been lower in more recent studies.¹³ Approximately 2% of all drug reactions are considered life-threatening.¹³ If considered in another way, drug reactions are relatively uncommon when the number of reactions per course of drug therapy is considered.¹² Another important facet is the drug interaction in which one drug affects the action of another, usually by causing increased or decreased plasma levels of that drug. This so-called 'pharmacokinetic reaction' usually results from the influence of one or more of the drugs on the cytochrome P450 isoenzyme system in the liver.¹⁴⁻¹⁶ Unlike adverse drug reactions, which are unpredictable in any specific patient, drug interactions are mostly known and can be avoided.¹⁷ Excellent reviews of the clinically significant drug interactions encountered in dermatology were published in 2006¹⁷ and 2008.¹⁸

Diagnosing drug reactions

Attribution of a cutaneous reaction to a particular drug may be difficult because many patients receive many drugs simultaneously.¹² Furthermore, many drug reactions mimic various dermatoses, most of which may have other causes. However, certain patterns are frequently caused by drugs: these include exanthematous reactions, urticaria, photosensitive eruptions, fixed drug eruptions, erythema multiforme, and toxic epidermal necrolysis.^{14,19} Other factors that may be used to identify the offending drug include cessation of the suspected drug (dechallenge), rechallenge with the suspected drug at a later time (provocation),²⁰ the use of specifically designed computer algorithms,²¹ a knowledge of drug reaction rates, and the morphology of lesions produced by particular drugs.^{9,22} Case reports, manufacturers' brochures, and reporting systems have all contributed to our knowledge of the various reactions produced by particular drugs.²²⁻²⁴ A valuable monograph, updated regularly, is the *Drug Eruption Reference Manual* by Jerome Z. Litt. Another important factor in

identifying an offending drug is the timing of events.²³ Most drug reactions occur within 10 days of receiving the offending agent, although longer periods have been recorded. Furthermore, some drug reactions may persist for weeks to months after use of the drug has ceased. This applies to lichenoid drug eruptions and particularly to reactions to gold.¹⁹

Provocation tests, whereby the patient is challenged with the drug suspected of causing the reaction, may provide confirmation in more than 50% of cases.²⁰ However, false-positive and false-negative reactions may occur, and there are also ethical considerations because in certain circumstances rechallenge may produce a severe anaphylaxis.²⁵ Some institutions are loath to give ethical approval for such procedures, although rechallenge is still being used to confirm the association in some countries.²⁶ Withdrawal tests are time-consuming if multiple drugs are involved.¹⁰

The shortcomings of *in vivo* testing and clinical observations have led to many studies being carried out to assess the reliability of various *in vitro* tests.¹⁰ Most have involved immunological methods because drug allergy is one mechanism involved in the pathogenesis of drug reactions. Some, such as skin testing, radioallergosorbent tests (RAST), and lymphocyte transformation studies, have been of limited diagnostic value.²⁶ Patch testing is usually of value only in allergic contact reactions, although positive patch tests have been found in up to 15% of patients with presumed drug reactions.²⁷ Positive reactions are more common with drugs such as β -lactams, clindamycin, and trimethoprim.²⁶ Prick and intradermal skin tests have also been used in the evaluation of drug reactions.²⁸

Drug-specific T cells may produce the inflammatory skin reaction through the production and release of different cytokines. Accordingly, T-cell-mediated sensitization to drugs may be assessed by assays based on cytokine release from peripheral blood lymphocytes.²⁹ One of the first tests used involved macrophage migratory inhibitory factor, but interferon- γ (IFN- γ) release²⁹ and interleukin-5 (IL-5) detection can be used. One of the most sensitive tests appears to be that for macrophage migration inhibition factor (MIF), a lymphokine that is released when sensitized T lymphocytes are challenged with the appropriate antigen.^{9,10,30} It is seen with cell-mediated and some immediate-type reactions.¹⁰ A positive MIF response to a variety of drugs has been found in 50–70% of patients with suspected drug eruptions but only in 5% of controls.¹⁰ IFN- γ release does not seem to be as accurate.²⁹ Tests based on the detection of drug-specific T-cell cytokines are a useful adjunct to clinical observations in detecting the offending drug. Among others, tests for drug hypersensitivity reactions include the lymphocyte toxicity assay, which can also detect a genetic predisposition to these types of reactions but is time-consuming, demanding of resources and reagents, and is therefore restricted to research centers; the basophil activation test, whose sensitivity has been enhanced by flow cytometry methods but is useful only in detecting reactions due to basophil activation and is available for a limited number of drugs; and the *in vitro* platelet toxicity assay, which has higher sensitivity than that of the lymphocyte toxicity assay but has not yet been validated for clinical use.³¹

Mechanisms of drug reactions

Various mechanisms, including toxic, metabolic, and allergic, have been implicated in the pathogenesis of cutaneous drug reactions.³² Certain patient groups are at an increased risk of developing an adverse drug reaction, including women, patients with Sjögren's syndrome, and those with AIDS.^{13,33-35} It has been suggested that 'pharmacogenetic variability' may account for a susceptibility to certain serious drug reactions.³³ Examples include glutathione synthetase deficiency (particularly in patients with AIDS) predisposing to sulfonamide reactions, epoxide hydrolase deficiency leading to the anticonvulsant hypersensitivity syndrome (see p. 600), and defects in drug acetylation

resulting in isoniazid reactions.³³ Most adverse effects, so-called *type A reactions*, are due to the pharmacological action of a drug.³⁶ A ‘toxic’ hypothesis does not explain all the characteristics of drug reactions.³⁷ For many substances, the mechanism is still uncertain. The term ‘idiosyncratic drug reaction’ has been used for unpredictable reactions that occur in only a small percentage of patients receiving the drug and that do not involve known pharmacological properties of the drug.³⁸ This term includes many of the reactions thought to have an immunological basis (see later). Such reactions are called *type B reactions*.

Immunological (allergic) mechanisms are thought to account for less than 20% of all cutaneous drug reactions despite the fact that positive tests for MIF (discussed previously) are found in more than 50% of suspected cases.^{5,10} This is because secondary immunological events may develop in the course of some drug reactions that basically are not of immunological pathogenesis.⁹

Immunological drug reactions have certain features that distinguish them from non-immunological reactions, although none is absolute.³⁹ They occur in only a small percentage of the population at risk; they may occur below the therapeutic range of the drug; and they appear after a latent period of several days, although this duration may be shorter on rechallenge.³⁹ Certain clinical patterns of drug reaction, such as systemic anaphylaxis, serum sickness, allergic and photoallergic contact dermatitis, fixed drug eruption, vasculitis, and the systemic lupus erythematosus-like syndrome, are characteristic of the immunological types of drug reaction.^{5,19,39,40} Urticaria may result from both immunological and non-immunological reactions, and some exanthematous reactions may have an immunological basis. The majority of allergic drug reactions are caused by antibiotics, blood products, anti-inflammatory agents, and inhaled mucolytics.¹¹

All four Gell and Coombs reactions may be involved in allergic reactions to drugs, although cutaneous reactions have not been clearly shown to be cytotoxic (type II reaction) in nature.^{5,40} The most significant drug reactions involve immediate hypersensitivity (type I reaction) and are IgE mediated.³² The best studied of this class of reaction is penicillin allergy, in which IgE antibodies to penicillin have been detected in the serum of affected individuals. Clinical manifestations of type I reactions include anaphylaxis, urticaria, and angioedema. Immune complexes (type III reaction) are involved in the pathogenesis of vasculitis, serum sickness, some urticarial and exanthematous reactions, systemic lupus erythematosus-like drug reactions, and possibly erythema multiforme and erythema nodosum, when due to drugs.^{32,40} Immunohistochemical analysis has identified CD8⁺ T cells as the predominant epidermal T-cell subset in drug-induced maculopapular and bullous eruptions.³⁰ However, more recent studies have isolated a heterogeneous population of CD4⁺ lymphocytes that are drug specific.^{41,42} The cells, when stimulated, produce IL-5. This cytokine may be responsible for the tissue eosinophilia often seen in drug reactions.⁴¹ It seems that CD8⁺ cells are not the predominant cell type, as once thought. CD1a⁺ dendritic cells have been found in the dermis in eruptions caused by some antibiotics.⁴³ Apart from exanthematous (morbilloform) drug reactions, delayed hypersensitivity (type IV reaction) is uncommonly the cause of drug reactions resulting from ingestion of a drug, although it is the usual mechanism involved following the topical application of a sensitizing drug.³² Type IV reactions may also be involved in fixed drug eruptions and in certain mixed reactions, as occur in erythema multiforme. The role of the type IV reactions has expanded since the recognition of subtypes of delayed hypersensitivity, an acknowledgment of the heterogeneity of T-cell function.³⁶ Pichler wrote an excellent paper on this subject.³⁶ Type IVa corresponds to Th1 reactions, type IVb to Th2 reactions, type IVc to cytotoxic reactions mediated by perforin and granzyme B, and type IVd reactions with IL-8 production, resulting in neutrophil recruitment and activation, resulting in pustular exanthema.³⁶ Some type IVc (cytotoxic)

Table 20.1 Correlation of Gell and Coombs reactions with clinical features (after Pichler)

Gell and Coombs	Immune response	Clinical symptoms
Type I	IgE	Urticaria, anaphylaxis
Type II	IgG and Fc receptor	No dermatological changes
Type III	IgG and complement	Vasculitis
Type IVa	Th1 (IFN- γ)	Eczema
Type IVb	Th2 (IL-5, IL-4)	Exanthematous reactions and bullous exanthema
Type IVc	Cytotoxic T cells (perforin and granzyme B)	Exanthematous reactions, eczema, bullous and pustular exanthema
Type IVd	T cells (IL-8)	Pustular exanthema

functions are present in all type IV reactions (Table 20.1). Upregulation of α -defensins 1–3 (microbicidal peptides that also influence macrophage function and the complement pathway) has been found in T cells from patients with Stevens–Johnson syndrome and toxic epidermal necrolysis and may be involved in the pathogenesis of these and other types of drug eruptions.⁴⁴

The offending drug, or a metabolite of it, acts as a hapten that combines with tissue or plasma protein to form a complete antigen, which in turn stimulates some part of the immune system.¹⁹ If the drug is of high molecular weight, it may be antigenic in itself. The method of administration of the drug and even environmental factors, such as an underlying infection or the presence of light of a suitable wavelength, may all influence the outcome.¹⁹ The integrity of the cutaneous nerves in a particular area also influences the distribution and expression of drug reactions. In patients with leprosy, the affected site is often spared in a drug reaction.⁴⁵ Unilateral involvement has been reported in a drug reaction to phenytoin in a patient with hemiplegia,⁴⁵ again emphasizing the importance of an intact nervous system in some drug reactions.

Much less is known about the non-immunological mechanisms involved in drug reactions. These may involve activation of effector pathways (e.g., opiates releasing mast cell mediators and NSAIDs altering arachidonic acid metabolism), overdose (as seen with hemorrhage produced by an excess of anticoagulants), metabolic alterations (isotretinoin affecting lipid metabolism and certain drugs affecting porphyrin metabolism), and cumulative toxicity (as seen with color changes resulting from the deposition of drug metabolites in the skin).¹⁹ Drugs may also exacerbate a pre-existing dermatological condition.¹⁹

CLINICOPATHOLOGICAL REACTIONS

Although the skin can react in only a limited number of ways, there are still a bewildering number of clinicopathological presentations of drug reactions.^{23,46} Usually, several drugs can produce any particular reaction, although certain drugs are more likely than others to give a particular pattern. The characteristics of the drug that determine which reaction is produced are largely unknown in the case of allergic drug reactions.

Although the important modifications of each of the major tissue reaction patterns induced by drugs are discussed in the respective chapters of this book, there are important clues common to a number of reaction patterns. They are shown in Table 20.2. A pattern

Table 20.2 Clues to a drug etiology
Eosinophils
Plasma cells (with some reactions)
Red cell extravasation (in 50% or more)
Apoptotic keratinocytes
Activated lymphocytes
Urticarial edema (in some reactions)
Endothelial swelling of vessels

analysis of the histological features of drug-induced skin diseases was published in 2008.⁴⁷ The various entities are considered elsewhere in this book.

The most common reactions produced by drugs are exanthematous in type, followed by urticaria and angioedema.¹ Fixed drug eruptions have been the third most common pattern in some series, although they have been much less frequent in others.¹ The most severe drug reactions are exfoliative dermatitis, the Stevens–Johnson syndrome, and toxic epidermal necrolysis. Sometimes, the clinical features of a drug reaction are difficult to characterize into one of the named patterns. Many of these are maculopapular in nature. They are often included in the exanthematous reaction, even though they do not strictly resemble a viral exanthem. Included in this group is the maculopapular eruption that may develop in the course of the treatment of leukemia,⁴⁸ corresponding to the stage of peripheral lymphocyte recovery.

The various reactions produced by drugs are discussed in other chapters with the exception of the exanthematous reactions, the vegetative lesions produced by halogens, and the drug hypersensitivity syndrome. These reactions are discussed in detail next, followed by a brief summary of the other cutaneous patterns produced by drugs.

EXANTHEMATOUS DRUG REACTIONS

Exanthematous eruptions (also described as morbilliform and as erythematous maculopapular eruptions) are the most common type of drug reaction, accounting for approximately 40% of all reactions.^{1,49} The rash develops 1 day to 3 weeks after the offending drug is first given, although the timing depends on previous sensitization.²³ Uncommonly, the onset is much later in the course of the drug therapy, and rarely it may develop after administration of the drug has ended.

There are erythematous macules and papules that resemble a viral exanthem. Lesions usually appear first on the trunk or in areas of pressure or trauma.¹⁹ They spread to involve the extremities, usually in a symmetrical manner. A publication has drawn attention to a distinct pattern of involvement of the upper arms in exanthematous drug eruptions.⁵⁰ Such eruptions involve the T1 dermatome with a sharp linear margin of demarcation from the spared skin served by the C5 spinal nerves. In short, there is medial involvement and lateral sparing. This so-called ‘drug line’ corresponds to the dorsoventral pigmentary demarcation line seen in approximately 20% of individuals with black skin but normally invisible in white skin and known as the Voigt–Futcher line.⁵⁰ Pruritus and fever are sometimes present. The eruption usually lasts 1 or 2 weeks and clears with cessation of the drug.¹⁹

Exanthematous eruptions occur in 50–80% of patients who are given ampicillin while suffering from infectious mononucleosis, cytomegalovirus infection, or chronic lymphatic leukemia or who are also taking allopurinol.³² Amoxicillin and salazosulfapyridine may sometimes produce a similar reaction in the same circumstances.^{51–53} An exanthematous eruption also occurs commonly in patients with

Figure 20.1 Exanthematous drug reaction characterized by focal basal spongiosis, mild exocytosis of lymphocytes, and a perivascular infiltrate of lymphocytes in the upper dermis. (H&E)

AIDS who are given co-trimoxazole (trimethoprim–sulfamethoxazole).^{2,54} It appears that patients with lymphotropic viral infections are at increased risk for cutaneous drug reactions.⁵⁵ Other drugs that cause an exanthematous reaction include penicillin, erythromycin, streptomycin, tetracyclines, bleomycin, amphotericin B, sulfonamides, oral hypoglycemic agents, thiazide diuretics, barbiturates, chloral hydrate, benzodiazepines, phenothiazines, ticlopidine,⁵⁶ codeine,⁵⁷ buserelin acetate,⁵⁸ allopurinol, thiouracil, quinine, quinidine, gold, captopril, and NSAIDs.^{23,59} *Ginkgo biloba* has also produced a diffuse morbilliform eruption.⁶⁰ Codeine and pseudoephedrine have produced an eruption resembling scarlet fever.⁶¹

The mechanisms involved in exanthematous reactions are now much clearer. There is a superficial, mainly perivascular lymphocytic infiltrate with a few eosinophils. CD4⁺ cells are mainly located in the perivascular dermis, whereas both CD4⁺ and CD8⁺ cells are found at the dermoepidermal junction in equal number.³⁶ The infiltrating T cells are very active expressing many cytokines. Cytotoxic T cells (more CD4 cells than CD8 cells) cause interface changes (cell death and vacuolar change) by a perforin-dependent and granzyme B-dependent killing mechanism.³⁶ Enhanced production of IL-5 by drug-specific T cells is common in different forms of drug allergies, including exanthematous reactions. This cytokine is a key factor in the maturation and activation of eosinophils.³⁶ Exanthematous reactions are largely of type IVc. An alternative theory, the p-i theory (pharmacologic interaction of drugs with immune receptors), suggests that small molecule drugs or metabolites thereof, although incomplete antigens, can activate T cells by binding directly to T-cell receptors.^{62,63}

Histopathology

At first glance, the histological changes in the exanthematous drug reactions appear nonspecific, but they are in fact quite characteristic. There are small foci of spongiosis and vacuolar change involving the basal layer with mild spongiosis extending one or two cells above this (Fig. 20.1).⁶⁴ A few lymphocytes are usually present in these foci.⁶⁴ A characteristic feature is the presence of rare apoptotic keratinocytes (Civatte bodies) in the basal layer (Fig. 20.2). Very focal parakeratosis may be present in lesions of some duration.

Figure 20.2 Exanthematous drug reaction. A Civatte body (apoptotic keratinocyte) and a few lymphocytes are present in the basal layer. (H&E)

The papillary dermis is usually mildly edematous, and there may be vascular dilatation. The inflammatory cell infiltrate, which consists of lymphocytes (some with large nuclei suggesting activation), macrophages, mast cells, occasional eosinophils and, rarely, a few plasma cells, is usually mild and localized around the superficial vascular plexus.⁶⁴

Epidermal changes may be minimal or even absent in scarlatiniform eruptions and in some nonspecific maculopapular eruptions categorized as exanthematous for convenience. A recent prospective study of exanthematous, maculopapular drug eruptions, with a reasonable level of clinical support for the diagnosis, expanded upon these microscopic findings. Epidermal changes included mild spongiosis, involving mostly lower levels of the epidermis, sometimes mild acanthosis, occasional intraepidermal neutrophils and lymphocytes, and discrete vacuolar alteration at the dermal–epidermal interface with rare apoptotic keratinocytes and scattered lymphocytes. Some dermal changes described in this study that are somewhat surprising include a deep as well as superficial dermal infiltrate in approximately one-fourth of the cases, discrete interstitial infiltrates, and more neutrophils than eosinophils in the papillary dermis.⁶⁵ A prominent neutrophilic component and a few enlarged lymphocytes were seen in eruptions due to anti-convulsants and anxiolytics.⁶⁵

HALOGENODERMAS

The term ‘halogenoderma’ includes iododerma, bromoderma,^{66,67} and the rare fluoroderma that result from the ingestion of iodides, bromides, and fluorides, respectively.⁶⁸ Iododerma is an uncommon disorder, whereas the other two are now exceedingly rare,⁶⁹ although there have been a number of recently reported cases of bromoderma developing in infants receiving potassium bromide therapy for seizure disorders.^{70–72} Verrucous plaques resembling those seen in the halogenodermas have recently been reported in two patients receiving long-term lithium therapy.⁷³

Three distinct types of cutaneous adverse reactions to bromides are seen: (1) acneiform papules, which may occur suddenly on the face but which may spread over the neck, chest, and arms; (2) granulomatous lesions, known as bromoderma tuberosum,⁷⁴ and (3) vegetative lesions.^{75,76}

The usual source of the iodide is the potassium salt used in expectorants and some tonics.⁷⁷ Rarely, radiocontrast media^{68,78} and amiodarone⁷⁹ have been implicated. It may be due to systemic absorption from topical iodine, such as the use of a sitz bath containing povidone-iodine.⁸⁰ The characteristic lesion is a papulopustule that progresses to a vegetating nodular lesion. This may be crusted and ulcerated. There are usually a number of lesions, 0.5–2 cm in diameter, on the face, neck, back, or upper extremities.^{68,77,81} The lesions clear with cessation of the halide. The mechanism involved in their pathogenesis is uncertain.⁶⁸

In addition to vegetating lesions, iodides may also produce erythematous papules, urticaria, vesicles, carbuncular lesions, erythema multiforme, vasculitis, polyarteritis nodosa, and erythema nodosum-like lesions.⁸² Iodides may also aggravate dermatitis herpetiformis, pyoderma gangrenosum, pustular psoriasis, erythema nodosum, and blastomycosis-like pyoderma.^{82,83}

A recent case of fluoroderma resulted from sevoflurane anesthesia; sevoflurane is metabolized into fluoride ions by oxidative defluorination through the cytochrome P450 pathway, with elevated serum inorganic fluoride concentrations as a result.⁸⁴ Lesions presented as ulcerated erythematous nodules in acral locations.

Histopathology⁷⁴

The vegetating lesions show pseudoepitheliomatous hyperplasia with intraepidermal and some dermal abscesses.^{85,86} The abscesses contain a few eosinophils and desquamated epithelial cells in addition to the neutrophils (Fig. 20.3). In early lesions, the ‘intraepidermal’ abscesses can be seen to be related to follicular infundibula. In the previously mentioned case of fluoroderma, findings included acanthosis and a dermal neutrophilic infiltrate without leukocytoclasia.⁸⁴

Differential diagnosis

There is considerable overlap in the microscopic configuration of the three forms of halogenoderma, and distinction among them requires additional clinical and laboratory information. As noted previously, on a percentage basis, iododerma seems to be the most common of these eruptions at the present time. Early or isolated pustular lesions raise the possibility of other pustular diseases, especially forms of pustular folliculitis. The combination of pseudoepitheliomatous hyperplasia and neutrophilic microabscesses is also seen in certain infectious diseases with a blastomycosis-like tissue reaction pattern, including North American blastomycosis, chromomycosis, sporotrichosis, blastomycosis-like pyoderma, or some atypical mycobacterial infections. However, although there may be occasional multinucleate cells in the dermis in halogenodermas, this is never as prominent a feature as it is in these infectious diseases. Pemphigus vegetans also shows marked acanthosis and intraepidermal abscesses, but in the latter disease eosinophils predominate, and focal acantholytic changes may be seen (though sometimes requiring careful search). Lesions with lesser degrees of acanthosis and a focally heavy superficial dermal neutrophilic infiltrate

Figure 20.3 Bromoderma and iododerma. (A) An example of bromoderma, showing pseudoepitheliomatous hyperplasia and a dense, neutrophil-rich dermal infiltrate. (B) In this example of iododerma, there is again pseudoepitheliomatous hyperplasia, with dermal edema, scattered macrophages, and lesser numbers of neutrophils compared to those in (A). This may represent an older lesion. (H&E)

(as can be seen in fluoroderma) may bear a resemblance to Sweet's syndrome, but they lack leukocytoclasia.⁸⁴

DRUG HYPERSENSITIVITY SYNDROME (DRUG RASH WITH EOSINOPHILIA AND SYSTEMIC SYMPTOMS (DRESS) SYNDROME)

A hypersensitivity reaction, characterized by fever, a generalized exanthem, and multiorgan toxicity, has been reported following the ingestion of a number of drugs, including phenytoin sodium, valproic acid and other anticonvulsants (see p. 605), carbamazepine, sulfonamides, dapsone, calcium channel blockers, nevirapine, allopurinol, and piroxicam.^{87–94} Allopurinol is the major cause of this syndrome in Taiwan.⁹⁵ Recent reports have also incriminated bellamine, which is used for menopausal symptoms;⁹⁶ teicoplanin used with vancomycin;⁹⁷ vancomycin alone;⁹⁸ abacavir;⁹⁹ clomipramine, a tricyclic antidepressant;¹⁰⁰ efalizumab;¹⁰¹ terbinafine;¹⁰² clopidogrel;¹⁰³ bosentan (a dual endothelin receptor antagonist used to treat pulmonary artery hypertension);¹⁰⁴ the β -lactam drugs ceftriaxone and piperacillin–tazobactam;¹⁰⁵ leflunomide;¹⁰⁶ the antiretroviral drug raltegravir;¹⁰⁷ lamotrigine;¹⁰⁸ first-line antituberculous therapy (isoniazid, rifampin, pyrazinamide, and ethambutol);¹⁰⁹ enoxaparin;¹¹⁰ deferasirox;¹¹¹ dipyrene;¹¹² nitrofurantoin;¹¹³ nevirapine;¹¹⁴ and potassium *para*-aminobenzoic acid.¹¹⁵ It is also known as the **DRESS syndrome** (drug rash with eosinophilia and systemic symptoms).¹¹⁶ It is an idiosyncratic reaction that is fortunately rare. It may be fatal. It may occur after prolonged use of the drug, but many cases occur within 1–8 weeks after the intake of an anticonvulsant.^{117,118} The exact pathogenesis is unknown. Some patients have a genetic deficiency of epoxide hydrolase, a hepatic enzyme that detoxifies the arene oxide metabolites of antiepileptic drugs.⁹⁶ Infection with human herpesvirus-6 (HHV-6) and possibly HHV-7, as well as other viruses such as Epstein–Barr virus and cytomegalovirus,^{99,119,120} may increase the risk of an individual developing this reaction (see p. 731).^{121–125} The HHV-6 genome may become integrated into the host's chromosomes.¹²⁶ Hypogammaglobulinemia may be associated with the reactivation of HHV-6.^{127–130} A blood eosinophilia is often present, and this appears to result from increased levels of IL-5.¹³¹ The occasional absence of eosinophilia calls into question the accuracy of the title DRESS syndrome.¹³² The lymphocyte transformation test may be a useful technique in identifying the responsible drug in selected cases.¹⁰⁵ Patch testing may also be useful in confirming the involved drug in DRESS syndrome due to antiepileptic agents, but apparently it is not of value when the culprit agent is allopurinol.¹³³

The skin lesions include a maculopapular eruption, toxic epidermal necrolysis, Stevens–Johnson syndrome, and facial edema. It has been reported in a premature infant on phenytoin,¹³⁴ as well as in older children.¹³⁵ Type 1 diabetes mellitus and the syndrome of inappropriate secretion of antidiuretic hormone may rarely develop as a consequence of the syndrome.^{136,137} A review of the clinical features, pathophysiology, and therapeutic aspects of DRESS syndrome has recently been published.^{138,139}

Histopathology

A number of histopathologic changes have been described in case reports of DRESS syndrome, and although there are some common themes among them, there is also significant variability of findings. A large, systematic study focused on histopathology is clearly in order. However, frequently reported features include a dense superficial dermal infiltrate (more dense than usually seen in common drug eruptions) that may be perivascular or band-like, extravasated erythrocytes, dermal edema, and sometimes small granulomas in the superficial dermal infiltrate.^{138,140} Epidermal changes include vacuolar alteration of the basilar layer¹¹⁰ and spongiosis with parakeratosis and subcorneal

pustule formation.¹⁴¹ In one case, a published figure shows significant apoptosis within the epidermis.¹³⁸ Eosinophils are often present in the dermal infiltrate but are not always prominent.¹⁴² In one case, there were microscopic features of drug-induced interstitial granulomatous dermatitis with eosinophils and focal vacuolar alteration of the basilar layer.¹⁴³ In other reports, the cutaneous pathology is simply described as ‘nonspecific’.¹⁴⁴

OTHER CLINICOPATHOLOGICAL REACTIONS

The following account details in alphabetical order the various clinicopathological patterns that have been associated with drugs.¹⁹ The reader should refer to the appropriate page, listed for each reaction, for an account of the clinical and histopathological features of each particular pattern and of the drugs that may be responsible.

Acanthosis nigricans

Various hormones and corticosteroids have been implicated in the etiology of some cases of acanthosis nigricans (see p. 587). There are no features that are specific for drug-induced lesions.

Acne

A number of drugs, cosmetics, and industrial chemicals may precipitate and influence the course of acne vulgaris (see p. 460). Sometimes, pustular acneiform lesions develop without the presence of comedones.

Alopecia

Numerous drugs have been implicated in the etiology of alopecia. Several different mechanisms may be involved (see p. 492). The best understood of these is the alopecia produced by the various antimitotic agents that interfere with the replication of matrix cells during anagen.

Bullous reactions

Blisters are an integral part of erythema multiforme, toxic epidermal necrolysis, and often fixed drug eruptions. Reactions resembling mucous membrane pemphigoid (see p. 182), pemphigus^{145,146} (see p. 149), and porphyria cutanea tarda (see p. 578) also occur. Bullae may develop in the course of drug-induced vasculitis or drug-induced coma (see p. 186). In addition to these circumstances, subepidermal bullae may also occur following the use of certain drugs (see p. 176).

Elastosis perforans serpiginosa

Lesions resembling elastosis perforans serpiginosa may be produced in patients receiving long-term penicillamine therapy (see p. 385).

Erythema multiforme

Drug-induced erythema multiforme is sometimes severe, with mucous membrane lesions and the clinical picture of the Stevens–Johnson syndrome (see p. 56). Target lesions are said to be less conspicuous in drug-related cases. The long-acting sulfonamides and various NSAIDs are often implicated.¹⁹

Erythema nodosum

Drugs have sometimes been implicated in the etiology of erythema nodosum (see p. 532). There are no distinguishing features of drug-induced lesions.

Erythroderma (exfoliative dermatitis)

Drugs are a significant cause of erythroderma, which usually commences some weeks after initiation of the drug (see p. 591). The rash often starts on the face and spreads over the rest of the body.

Figure 20.4 Interstitial granulomatous drug reaction. There is a close resemblance to the incomplete form of granuloma annulare. (H&E)

Fixed drug eruptions

There may be one or several sharply demarcated lesions, beginning as dusky patches, which fade, leaving an area of pigmentation (see p. 53). The lesion recurs in the same area after rechallenge with the drug. Urticarial and bullous forms have been described.

Granulomas

Rarely, a granulomatous tissue reaction is related to the ingestion of drugs, including the sulfonamides and allopurinol. Elastophagocytosis occasionally accompanies a drug reaction in sun-damaged skin. Granulomas may follow the local injection of various drugs, including toxoids containing aluminum salts. The interstitial granulomatous drug reaction is a distinctive clinicopathological entity (see p. 216) that histologically resembles the incomplete form of granuloma annulare (**Fig. 20.4**).¹⁴⁷

Hypertrichosis

Hypertrichosis, usually facial, may occur with certain drugs, of which minoxidil and oral contraceptives are the most familiar. Occasionally, the hypertrichosis is permanent, although it usually subsides following cessation of the drug (see p. 497).

Infarction

Hemorrhagic infarction of the skin is an uncommon complication of anticoagulant therapy (see p. 222). It usually occurs in the first week of therapy.²³

Lichenoid drug eruption

The lichenoid reaction resembles lichen planus to a variable degree (see p. 52). Sometimes there is a slightly scaly (‘eczematous’) appearance to the lesions. Postinflammatory pigmentation is more prominent than in lichen planus.

Lipodystrophy

A lipodystrophy has been reported in patients infected with HIV, following treatment with protease inhibitors (see p. 545).

Lupus erythematosus-like reaction

A disease resembling lupus erythematosus can be precipitated by several drugs (see p. 69). Procainamide-induced lupus erythematosus, which is the best studied, has a low incidence of renal involvement.

Neutrophilic eccrine hidradenitis

Neutrophilic eccrine hidradenitis is a rare complication of induction chemotherapy used in the treatment of certain types of cancer (see p. 505). Cytarabine has been the most frequently implicated drug.

Panniculitis

A panniculitis may result from the injection of certain drugs (see p. 554) and from the withdrawal of corticosteroids (post-steroid panniculitis) (see p. 544). Drugs including thiazides, sulfonamides, corticosteroids, oral contraceptives, and sulindac may cause a pancreatitis that in turn may be associated with a panniculitis (see p. 541). Erythema nodosum (discussed previously) is a specific pattern of panniculitis sometimes associated with drug ingestion.

Photosensitivity

Phototoxic and photoallergic variants have been recognized (see p. 622). Although the lesions in the various stages of photosensitivity are most marked in areas exposed to the sun (Fig. 20.5), they sometimes extend to areas protected from the sun; this is particularly the case in photoallergic dermatitis.^{148,149} Some persistent light reactions are drug induced (see p. 627).

Figure 20.5 (A) Photosensitive drug eruption. (B) There are rare apoptotic keratinocytes, solar elastosis, and stellate 'fibroblasts'. (H&E)

Pigmentation

Several mechanisms are involved in the cutaneous pigmentation produced by drugs, including an increased formation of melanin, melanin incontinence, and the deposition of drugs or drug complexes.²³ Antimalarials, phenothiazines, tetracycline and some of its derivatives, amiodarone, clofazimine, and various antineoplastic chemotherapeutic agents may all produce cutaneous pigmentation. Coadministration of minocycline and amitriptyline may accelerate cutaneous pigmentation (see p. 450).¹⁵⁰

Porphyria

Certain drugs may provoke attacks in patients who have porphyria cutanea tarda or porphyria variegata or in carriers of the genetic defect (see p. 577).

Pseudoacromegaly

Pseudoacromegaly, which is the presence of acromegaloid features in the absence of elevated growth hormone or insulin-like growth factor levels, has resulted from the long-term use of minoxidil, which is used for the treatment of hypertension.¹⁵¹

Pseudolymphoma

Drug-induced cutaneous pseudolymphoma is an uncommon reaction (Fig. 20.6). It is seen most often with the antiepileptic drugs,¹⁵² such as phenytoin and carbamazepine. It has also been reported with valproate sodium, atenolol, griseofulvin, imatinib,¹⁵³ ACE inhibitors, allopurinol, cyclosporine (ciclosporin), antihistamines, mexiletine, benidipine,¹⁵⁴ and the tumor necrosis factor- α (TNF- α) inhibitors adalimumab and infliximab¹⁵⁵ (see p. 1211). Pseudoclonality occurs in a number of cases so that interpretation of clonality studies needs to be correlated with morphology and clinical circumstances.¹⁵⁶ Resolution of the lesions takes longer than for other patterns of drug reactions, with some cases persisting for 6 months or more after cessation of the offending drug.¹⁵⁷

Psoriasiform drug reactions

Various drugs, particularly lithium, may precipitate or exacerbate psoriasis (Fig. 20.7) and pustular psoriasis (see p. 91). The withdrawal of steroids may also precipitate pustular psoriasis. Sometimes the β -blockers produce a clinical pattern resembling psoriasis, although the histological picture is lichenoid or mixed lichenoid and psoriasiform in type. Acrodermatitis continua of Hallopeau has resulted from the use of terbinafine.¹⁵⁸

Purpura

Purpura may result from damage to the vascular endothelium, thrombocytopenia, or both. Vasculitis is another association, although this produces a so-called 'inflammatory purpura'; in the non-inflammatory purpuras, there is simply an extravasation of red blood cells (see p. 220).

Pustular lesions

Pustules, usually resembling subcorneal pustular dermatosis on histopathological examination, have been reported with diltiazem, isoniazid, and cephalosporins (see p. 142). Subcorneal, intraepidermal, and even subepidermal pustules can be seen in acute generalized exanthematous pustulosis. Numerous drugs have been incriminated (see p. 145).

Sclerodermoid lesions

Sclerodermoid lesions may develop following occupational exposure to polyvinyl chloride and certain other chemicals and also following

Figure 20.6 Pseudolymphoma. (A) There is a dense dermal lymphocytic infiltrate with vascular prominence. (B) Higher power view, showing plasma cells and numerous eosinophils in addition to lymphocytes. (H&E)

the use of bleomycin. Local sclerodermoid reactions may result from the injection of phytanadione (phytomenadione) or pentazocine (see p. 360).

Spongiotic reactions

Spongiotic reactions are seen with allergic and photoallergic contact reactions and in systemic contact dermatitis¹⁵⁹ (see p. 129). Uncommonly, drugs may exacerbate or precipitate a named spongiotic disorder such as seborrheic dermatitis or nummular dermatitis. The pityriasis rosea-like reactions (see p. 112) can also be included in this group. Certain drugs may produce a spongiotic reaction with histopathological features (Fig. 20.8) that enable it to be distinguished from other spongiotic disorders (see p. 128).

Sweat gland necrosis

Sweat gland necrosis (Fig. 20.9) may occur in certain drug-induced comas (see p. 186).

Figure 20.7 (A) Psoriasis precipitated by the ingestion of lithium carbonate. (B) There is greater exocytosis of neutrophils and less regular psoriasiform hyperplasia than is usually seen in psoriasis. (H&E)

Figure 20.8 Spongiotic drug reaction following the ingestion of a thiazide diuretic. Note the conspicuous exocytosis of lymphocytes associated with the focus of spongiosis. (H&E)

Figure 20.9 Sweat gland necrosis in a patient comatose from a drug overdose. Squamous metaplasia is developing in several glands. (H&E)

Toxic epidermal necrolysis

Toxic epidermal necrolysis is the most serious cutaneous reaction to drugs. Large areas of the skin are sloughed, and this is usually preceded by the development of large flaccid bullae²³ (see p. 59). Sulfonamides, allopurinol, and NSAIDs are most often implicated.

Ulceration

Ulceration is an extremely rare complication of drugs. Allopurinol has been incriminated in the formation of a foot ulcer, resulting from a peripheral neuropathy.¹⁶⁰ Hydroxyurea is another cause of leg ulceration (see p. 277).

Urticaria

Urticaria is second only to drug exanthems as a manifestation of drug reactions. Numerous drugs have been responsible (see p. 230). Insulin has become an uncommon cause of urticarial reactions, since the development of the contaminant-free, human preparations.¹⁶¹ The mechanisms involved include IgE-dependent reactions, immune complexes, and the non-immunological activation of effector pathways involved in mast cell degranulation.¹⁹

Vasculitis

The usual presentation of vasculitis is with 'palpable purpura' on the lower parts of the legs.¹⁶² Immune mechanisms, particularly a type III reaction, are involved. Numerous drugs may produce a vasculitis (see p. 234).

Wound healing

Various drugs can influence wound healing. Adverse effects may be produced by corticosteroids, colchicine, cytotoxic drugs, and antibiotics.¹⁶³

OFFENDING DRUGS

The drugs that most often produce cutaneous reactions are antibiotics, NSAIDs, psychotropic agents, β -blockers, and gold.^{1,4,164} Other important drugs are thiazide diuretics,¹⁶⁵ antimalarial drugs,^{166,167} calcium channel blockers,^{87,168} ACE inhibitors, angiotensin II receptor antagonists,¹⁶⁹ phenytoin and derivatives, recombinant cytokines,¹⁷⁰ and anti-cancer chemotherapeutic agents.¹⁷¹ Herbal remedies are an increasingly important cause of cutaneous reactions.¹⁷²

Some drugs have a low incidence of reactions. Knowledge of these drugs may assist in determining the offending drug in patients receiving multiple therapeutic agents. Drugs in this category include antacids, antihistamines,¹⁷³ atropine, digitalis glycosides,¹⁶⁵ insulin (regular), nystatin, potassium chloride, steroids, tetracycline, theophylline, thyroxine, vitamin preparations, and warfarin.^{23,32}

Brief mention is made next of the major categories of offending drugs as well as the retinoids, recombinant cytokines, intravenous immunoglobulin, monoclonal antibodies, protease inhibitors, and botulinum toxin – all emerging areas of importance.

Antibiotics

Antibiotics are the major cause of drug reactions, accounting for 42% of all reactions in one series involving hospital inpatients.⁴ Co-trimoxazole (trimethoprim-sulfamethoxazole) produced the highest number of reactions in one study (59 reactions/1000 recipients), whereas the frequency for ampicillin was 52/1000 and for the semisynthetic penicillins 36/1000.⁵ In another study, amoxicillin resulted in the highest number of reactions (51/1000 patients exposed).¹¹ In a recent study of 472 children with rashes following antibiotic exposure, the frequency of an eruption was 12.3% for cefaclor, 2.6% for other cephalosporins, 7.4% for penicillins, and 8.5% for sulfonamides.¹⁷⁴ The macrolides (erythromycin, clarithromycin, roxithromycin, and azithromycin) have a low incidence of cutaneous side effects.¹⁷⁵

The most common pattern of skin reaction caused by antibiotics is an exanthematous one, but most other clinicopathological patterns have been reported at some time.^{176–182} Approximately 10% of cases of urticaria are caused by drugs, the most common (among antibiotics) being produced by penicillins and sulfonamides.¹⁸³ In the case of the tetracyclines, photosensitivity and fixed drug eruptions are sometimes seen.¹⁹ Skin and mucous membrane pigmentation, a lupus-like reaction, and a hypersensitivity syndrome have been reported with minocycline.^{184–187} In one case, minocycline hypersensitivity was associated with hypotension.¹⁸⁸ The high incidence of reactions in patients taking ampicillin who also have infectious mononucleosis, cytomegalovirus infection, or chronic lymphatic leukemia has been referred to previously. In the case of co-trimoxazole (trimethoprim-sulfamethoxazole), two distinct eruptions have been recorded: an urticarial reaction with onset a few days after the beginning of treatment and an exanthematous (morbilliform) reaction with its onset after 1 week of treatment.⁵⁴ Toxic epidermal necrolysis has also been reported with this drug.¹⁸⁹ There is a high incidence of reactions to this drug in patients infected with HIV.^{190,191} Risk factors for the development of cutaneous drug reactions to sulfonamides in patients with AIDS include high CD8⁺ cell count and age younger than 36 years.¹⁹² In a recent study from Thailand involving 191 patients, the most common cutaneous reaction to sulfonamide antibiotics was a maculopapular eruption (38%), followed by fixed drug eruption (22%), angioedema (13%), and urticarias alone (12%). Maculopapular eruptions were most common in the HIV-positive group, whereas fixed drug eruptions were more frequent among HIV-negative individuals. Positive HIV serology and lower CD4 counts were associated with an increased risk or more serious cutaneous reactions.¹⁹³ Note that celecoxib, a cyclooxygenase (COX)-2 inhibitor, contains a sulfonamide moiety and may give similar reactions.¹⁹⁴

Other cutaneous reactions produced by antibiotics include an intertriginous eruption due to amoxicillin,¹⁹⁵ photosensitivity reactions with fluoroquinolones,¹⁹⁶ a severe anaphylactic reaction to topical rifamycin in a patient with hypersensitivity to ciprofloxacin,¹⁹⁷ and the 'red man/red neck' syndrome following the rapid infusion of vancomycin.¹⁹⁸

Adverse reactions have been reported to the new oral antifungal agents. Cutaneous reactions including urticaria, erythema, and pruritus have been reported in 2.3% of patients taking terbinafine.^{199,200} Isolated reports of erythema multiforme, toxic epidermal necrolysis, fixed

drug eruptions, acute generalized exanthematous pustulosis, generalized pustular psoriasis,²⁰¹ dermatomyositis, an erythema annulare centrifugum-like psoriatic drug eruption, a hypersensitivity reaction, and alopecia, resulting from terbinafine, have appeared.²⁰²⁻²⁰⁵

Many of these reactions have also been reported with the oral antifungal agents fluconazole and itraconazole.¹⁹⁹ In particular, itraconazole can produce acute generalized exanthematous pustulosis, a purpuric eruption, and erythematous papules.²⁰⁶⁻²⁰⁸ Fluconazole has been associated with erythema multiforme, toxic epidermal necrolysis, erythroderma, angioedema,¹⁹⁹ and, particularly, fixed drug eruption.²⁰⁹⁻²¹¹ Beau's lines have been reported on the digits following the use of itraconazole.²¹² A hypersensitivity reaction has been produced by terbinafine.¹⁰²

The antiviral agent foscarnet produces penile ulcers in a high proportion of those who take it. Erosions of the vulva have also been reported.²¹³ A recall dermatitis restricted to the dermatomes previously affected by herpes zoster has followed the oral administration of acyclovir (aciclovir).²¹⁴ The 'isotopic response' is a similar phenomenon.²¹⁵

Nonsteroidal anti-inflammatory drugs

NSAIDs are a chemically heterogeneous group of compounds that can produce a variety of cutaneous reactions ranging from mild exanthematous eruptions to life-threatening toxic epidermal necrolysis.^{216,217} They are among the most commonly prescribed class of drugs, accounting for approximately 5% of prescriptions dispensed in the United States.^{59,217} Several drugs in this category have already been withdrawn from the market because of their cutaneous reactions.

The following categories of NSAIDs are in use:²¹⁷

- *Salicylic acid derivatives*: aspirin and various compound analgesics
- *Heterocyclic acetic acids*: indomethacin, sulindac, and tolmetin
- *Propionic acid derivatives*: ibuprofen, naproxen, and fenoprofen
- *Anthranilic acids*: mefenamic acid, flufenamic acid, and meclofenamate sodium
- *Pyrazole derivatives* (pyrazolones): phenylbutazone and oxyphenbutazone
- *Oxicams*: piroxicam
- *COX-2 inhibitors*: celecoxib, etodolac, meloxicam, rofecoxib, and valdecoxib.

Drugs belonging to any given chemical group frequently share similar mechanisms of action and toxicity. NSAIDs inhibit the enzyme cyclooxygenase and thus reduce production of prostaglandins and thromboxanes; this action is not solely responsible for their therapeutic actions.⁵⁹

Exanthematous eruptions are commonly seen with phenylbutazone and indomethacin, but they have been reported with most of the other NSAIDs.¹⁹ Aspirin is an important cause of acute urticaria; it also aggravates chronic urticaria.²¹⁷ The propionic acid derivatives ibuprofen and naproxen can both produce fixed drug eruptions.^{218,219} Bupropfen may produce a vasculitis, morbilliform eruption, urticaria, erythema multiforme, erythema nodosum, a bullous eruption, or a lupus erythematosus-like eruption;²²⁰ naproxen may produce a lichenoid reaction or a vesiculobullous reaction.²¹⁷ Piroxicam may result in a vesiculobullous eruption in areas exposed to the sun.⁵⁹ It has also resulted in an aphthous stomatitis.²²¹ Most of the NSAIDs have been reported to cause toxic epidermal necrolysis and/or erythema multiforme at some time, although the substances most frequently responsible are the pyrazolones.^{19,59} The COX-2 inhibitors can produce a wide range of reactions from exanthematous lesions to urticaria and toxic epidermal necrolysis. Valdecoxib has been associated with a hypersensitivity syndrome reaction.²²² Celecoxib has caused a pustular folliculitis eruption.²²³ This class of drugs may give reactions with few, if any, eosinophils (personal observation).

Psychotropic drugs

The psychotropic drugs include the tricyclic antidepressants, antipsychotic drugs, lithium, and the hypnotic and anxiolytic (tranquilizer) agents.²²⁴ This group of drugs produces the most diverse range of reactions, which include exacerbation of porphyria (chlorthalidoxepoxide), blue-gray discoloration of the skin (chlorpromazine), and an acneiform eruption (lithium).^{224,225} Further mention of the specific complications of the various drugs in this category is made in the description of the appropriate tissue reaction.

Phenytoin sodium and anticonvulsants

Phenytoin sodium is a widely prescribed anticonvulsant with a relatively low rate of side effects. Nevertheless, a broad spectrum of cutaneous reactions has been reported.²²⁶ These include exanthematous eruptions, acneiform lesions, exfoliative dermatitis, erythema multiforme, toxic epidermal necrolysis, vasculitis, hypertrichosis, gingival hyperplasia, coarse facies, heel-pad thickening, a lupus erythematosus-like reaction, digital deformities²²⁷ (the fetal hydantoin syndrome), a hypersensitivity syndrome,^{228,229} and a pseudolymphoma syndrome.²²⁶ Carbamazepine, lamotrigine, phenobarbital (phenobarbitone), and primidone cause similar side effects to phenytoin sodium, including a hypersensitivity syndrome – 'the anticonvulsant hypersensitivity syndrome'.^{93,230-235} This syndrome is considered further with the drug hypersensitivity syndrome (see p. 600). Generalized pustulation is one manifestation of the syndrome.^{236,237} Phenytoin sodium has also resulted in cutaneous necrosis with multinucleate epidermal cells at the site of intravenous infusion.²³⁸ Among the various medications in this group, carbamazepine is associated with the highest number of adverse cutaneous reactions (10 or 11%).²³⁹

Gold

Gold produces a variety of cutaneous reactions that are most commonly 'eczematous' or maculopapular in type.²⁴⁰ These reactions may occur as long as 2 years after the initiation of therapy.¹⁹ The lesions may take months to resolve.¹⁹ Other reactions produced by gold include cutaneous pigmentation, exfoliative dermatitis, vasomotor flushing, a lichenoid drug reaction, erythema nodosum, and an eruption resembling pityriasis rosea.²⁴¹

Macrolactams (calcineurin inhibitors)

The macrolactams, pimecrolimus and tacrolimus, are used in the treatment of atopic dermatitis and allergic contact dermatitis. Unlike topical corticosteroids, they do not produce skin atrophy. Side effects are mild and uncommon, but there is one report of a rosacea-like granulomatous reaction following the topical use of tacrolimus.²⁴² Both drugs inhibit the synthesis of inflammatory cytokines, especially Th1 and Th2 cytokines. This occurs through a complex pathway involving the blocking of calcineurin.²⁴³ For this reason, these drugs are also known as topical calcineurin inhibitors (TCIs). These drugs are also inhibitors of gli-1 signaling. There is no conclusive evidence from rodent trials that the long-term application of TCIs is photocarcinogenic.^{244,245} Sirolimus (rapamycin), discovered in fungi in remote Easter Island, acts as an inhibitor of vascular endothelial growth factor.²⁴⁶ It is mentioned here solely because it may be superior as an immunosuppressant to the calcineurin inhibitors.

Retinoids

Retinoids are a group of compounds that produce their biological responses via a specific receptor whose usual bindings are retinol and retinoic acid.²⁴⁷ Synthetic retinoids such as etretinate, tretinoin, and isotretinoin are of increasing importance in dermatological therapy.

They have received widespread media coverage because of their ability to improve photoaged skin. They can also stimulate granulation tissue in chronic wounds, promoting wound healing.²⁴⁸

Retinoids produce multiple changes, including a reduction in the keratin content of keratinocytes and in epidermal hyperplasia, and an increase in Langerhans cells, dermal collagen, tropoelastin, and angiogenesis. They produce reduced collagenase and gelatinase activity and glycosaminoglycans.²⁴⁷

Retinoids appear to cause partial regression of established skin cancers and to inhibit the number of skin cancers that appear in susceptible individuals, such as those with xeroderma pigmentosum, as long as the treatment is continued.²⁴⁷ The author was involved in an early clinical trial of retinoic acid, which was aborted when multilobate nuclei were found in the epidermis of individuals treated with topical retinoic acid for 1 year. This observation was never published.

Cutaneous side effects of synthetic retinoids include cheilitis, palmo-plantar peeling, pyogenic granuloma-like lesions in acne, alopecia, and paronychia.^{247,249} Granulation tissue may form in the palpebral conjunctivae.²⁵⁰ Induction therapy with all-*trans*-retinoic acid in patients with acute promyelocytic leukemia can produce a range of scrotal lesions, including ulceration, exfoliative dermatitis, and Fournier's gangrene.^{251,252}

Cytotoxic drugs

Cytotoxic drugs used in the treatment of cancer have many mucocutaneous complications. Because combination chemotherapy is often used, it may be difficult to determine which drug is specifically responsible for a particular reaction. There is evidence that some of the rashes attributed to drugs in the past may be examples of the eruption of lymphocyte recovery (see p. 63). It is still possible that a drug is responsible for these eruptions, in some cases, and that the reaction is only expressed when the number of immunocompetent cells returns to a sufficient level.^{253,254} Their action on rapidly dividing cells means that cytotoxic drugs commonly produce alopecia, stomatitis, apoptotic keratinocytes, and Beau's lines on the nails.^{171,255} Chemical cellulitis, ulceration, and phlebitis may result from local extravasation into the tissues of injected drugs.²⁵⁶ Vinca alkaloids, such as vincristine, vinblastine, and its semisynthetic analogue vinorelbine, have the highest potential for producing skin necrosis of all the anticancer drugs.²⁵⁷

Other complications of cytotoxic drugs include alterations in cutaneous pigmentation (see p. 452), nail pigmentation,²⁵⁸ neutrophilic eccrine hidradenitis (see p. 505), eccrine squamous syringometaplasia (see p. 505), sclerodermoid reactions (see p. 360), urticaria, vasculitis, erythroderma, inflammation of keratoses (see p. 797),²⁵⁹ enlarged dermal macrophages,²⁶⁰ and exacerbation of porphyria (see p. 577).^{171,255} Erysipeloid lesions are produced by the nucleoside analogue gemcitabine.²⁶¹ Pediatric patients sometimes develop an intertriginous eruption in association with various chemotherapeutic agents.^{262,263} Children receiving high-dose thiopeta, an alkylating agent, often develop a diffuse erythema followed by desquamation and hyperpigmentation.²⁶⁴

Lichenoid dermatitis and maturation arrest due to cytotoxic drugs

The most common type of chemotherapy reaction, encountered across a number of classes of agents, is lichenoid dermatitis, which includes several manifestations of dyskeratosis or so-called 'maturation arrest'. The clinical presentations of these eruptions can vary widely and include a lichen planus-like eruption (FT-207 (a modified form of 5-fluorouracil), hydroxyurea, and imatinib), maculopapular eruptions (busulfan, cytarabine, and bleomycin), a 'scaly follicular eruption' (liposomal doxorubicin), and a localized dermatitis (dacarbazine). An acral erythema (chemotherapy-induced acral erythema), or hand-foot

syndrome, has been reported from the use of certain chemotherapeutic agents, such as docetaxel, cyclophosphamide, fluorouracil and its prodrug tegafur, doxorubicin,²⁶⁵ cisplatin,²⁶⁶ methotrexate,^{267,268} and cytarabine (cytosine arabinoside).^{269,270} Discrete, erythematous to violaceous patches or plaques involve palms and soles, dorsa of the hands and feet, and sometimes other locations. The lesions subside within 1 or 2 weeks following discontinuation of chemotherapy, with eventual desquamation. The fixed erythrodysesthesia produced by the combination of gemcitabine and epirubicin is probably a variant of acral erythema.²⁷¹ Another form of acral erythema is associated with the multikinase inhibitors sorafenib and sunitinib. This is apparently clinically distinctive from other varieties of acral erythema in that plaques are more discrete and hyperkeratotic, although there appears to be at least some histopathologic overlap (see later discussion of **recombinant cytokines**). Another lesion known as *fixed erythrodysesthesia plaque* arises proximally to the site of intravenous infusion of docetaxel; it slowly resolves, leaving residual hyperpigmentation and desquamative changes.²⁷² An erythrodysesthesia with histological epidermal dysmaturation has also been produced by Doxil® (see later).²⁷³ A bullous reaction is rare.^{268,274,275} Acral erythema appears to be a common side effect of doxorubicin when it is encapsulated in liposomes (Doxil®).^{259,276}

Histopathology

Some examples of chemotherapy-induced lichenoid eruptions closely resemble lichen planus (e.g., FT-207) (**Fig. 20.10**). There may also be a combination of interface dermatitis with interstitial dermal inflammation, as described in reactions to the proteasome inhibitor bortezomib,²⁷⁷ or mixed spongiotic and interface changes, as described in some examples of acral erythema and erythrodysesthesia plaque.²⁷⁸ Lesions with dysmaturation often show vacuolar alteration of the basilar layer and disorganized keratinocytes with large amounts of cytoplasm, enlarged or otherwise atypical nuclei, necrotic or apoptotic cells, and a lack of orderly maturation with ascent to more superficial portions of the epidermis. Large areas of the epidermis may be involved, or the changes may consist of scattered keratinocytes with large vesicular nuclei and prominent nucleoli – 'busulfan cells'²⁷⁹ or 'starburst' mitoses as seen with etoposide therapy.²⁸⁰ Squamous syringometaplasia may accompany or be the predominating feature of some chemotherapy reactions; implicated agents include cytarabine, bleomycin,²⁸¹ imatinib,²⁸² liposomal doxorubicin,²⁸³ and vincristine²⁸⁴ (**Fig. 20.11**).

Figure 20.10 Chemotherapy-induced lichenoid eruption. This lichenoid tissue reaction is due to etoposide. (H&E)

Figure 20.11 Squamous syringometaplasia. The changes in this case were due to bleomycin therapy. (H&E)

It has been suggested that natural killer cells initially target keratinocytes in the eccrine apparatus, producing small spongiotic vesicles adjacent to the acrosyringium, apoptosis of cells at all levels of the eccrine apparatus, and later squamous syringometaplasia.²⁸⁵ Epidermal dysmaturation is sometimes produced (Fig. 20.12).²⁸⁶ A close relationship between squamous syringometaplasia and neutrophilic eccrine hidradenitis has been postulated (see previous section on **neutrophilic eccrine hidradenitis**); several agents produce both reactions (e.g., cytarabine and bleomycin).²⁸⁷

Differential diagnosis

Lesions with distinctly lichenoid features need to be distinguished from true lichen planus, lichenoid drug eruption due to non-antineoplastic agents, or, in the case of solitary lesions, lichenoid keratosis. When there is a combination of lichenoid and spongiotic changes, certain viral exanthems, such as the one that accompanies Gianotti-Crosti syndrome, are included in the differential diagnosis. Epidermal dysmaturation occupying a broad front of epidermis could be confused with actinic keratosis, but often the latter shows some stretches with atypia confined to basilar epidermis – a change not expected in chemotherapy reactions. In addition, the extreme cellular and nuclear pleomorphism of Bowen disease is not observed, and the acantholysis of Grover disease, Darier disease, or other forms of focal acantholytic dyskeratosis is not apparent. Squamous syringometaplasia has been described in a number of clinical situations unrelated to chemotherapy

Figure 20.12 Epidermal dysmaturation. (A) Some large epidermal cells are present. The patient had received chemotherapy a few weeks earlier. The biopsy was done for an associated drug reaction, subtle features of which are also present. (B) Dysmature keratinocytes are present at different levels of the epidermis. (H&E)

or malignancy;²⁸⁸ examples include burns,²⁸⁹ phytophotodermatitis,²⁹⁰ and administration of nonsteroidal anti-inflammatory agents.²⁹¹ Chemotherapy reactions of the dysmaturation type should also be distinguished from graft-versus-host disease. Both can feature lichenoid dermatitis, including vacuolar alteration of the basilar layer and formation of apoptotic keratinocytes. However, cytologic atypia and loss of orderly keratinocyte maturation are not microscopic criteria for graft-versus-host disease. One case the editor reported of non-ulcerated epidermal dysmaturation due to pegylated liposomal doxorubicin showed numerous neutrophils in the dermal infiltrate; this is not generally reported as a finding in graft-versus-host disease, but further study is needed to determine if this might be a valid differentiating feature. However, keratinocyte dysmaturation can sometimes be seen in patients with graft-versus-host disease who have not received cytoreductive therapy.²⁹² Furthermore, because chemotherapy effects on the epidermis may be sporadic and not associated with significant clinical disease, they can be found coincidentally in biopsies performed to evaluate for possible graft-versus-host disease. For this reason, Horn

recommends avoiding areas of chemotherapy effect, if possible, when microscopically searching for changes of graft-versus-host disease.²⁹³

Other reactions to cytotoxic drugs

Intradermal bleomycin results in necrosis and apoptosis of epidermal keratinocytes and eccrine epithelium. There is an associated neutrophilic infiltrate around the sweat glands, resembling neutrophilic eccrine hidradenitis (see p. 505).²⁹⁴ Bleomycin, peplomycin, and docetaxel may also produce a flagellate erythema followed by hyperpigmentation.^{295–297} The flagellate dermatitis has microscopic features resembling those of fixed drug eruption: vacuolar alteration of the basilar layer and apoptotic keratinocytes, followed by melanin incontinence. A recent report described spongiosis, vesicle formation, and exocytosis of neutrophils – features that have also been described as an alternative microscopic configuration of fixed drug eruption.²⁹⁸

A linear, serpentine erythematous eruption overlying the superficial veins of both arms has been reported following the intravenous use of 5-fluorouracil.^{299,300} The changes have been called ‘persistent supravenuous erythematous eruption’. The histological changes resemble erythema multiforme. A similar reaction limited to the arm of cytotoxic infusion has been produced by docetaxel.³⁰¹ A related condition, termed ‘serpentine supravenuous pigmentation’, has also been associated with 5-fluorouracil; other agents reported to produce this eruption include fotemustine, vinorelbine, and triazinate.³⁰² Subungual hemorrhages and abscesses have been reported as a side effect of docetaxel therapy.^{303,304} Extravasation of docetaxel during intravenous administration can produce a vesicant-like hemorrhagic eruption.³⁰⁵ An exudative hypopycnial dermatitis has also been reported with the combination of docetaxel and capecitabine.³⁰⁶ A recall dermatitis has been induced by docetaxel at previous laser treatment sites.³⁰⁷ Ultraviolet recall dermatitis developed in a patient receiving methotrexate and cytarabine.³⁰⁸

Methotrexate, when used in the treatment of autoimmune diseases, may be associated with the development of various lymphoproliferative disorders.³⁰⁹

Cladribine, a purine analogue used in the treatment of hairy cell leukemia and now some other leukemias, can produce eosinophilic cellulitis with flame figures, resembling Wells’ syndrome.³¹⁰

Mesna, a mercaptoalkane sulfonic compound used to lessen the urotoxic effects of drugs such as cyclophosphamide, produces urticarial reactions and a generalized fixed drug eruption.³¹¹

Imiquimod, a toll-like receptor-7 agonist, is used in the treatment of actinic keratoses and superficial cutaneous tumors. Localized irritant reactions are common and may lead to discontinuation of therapy. Numerous inflammatory papules may develop in the skin surrounding the treatment site.³¹² A localized contact pemphigus is a rare complication. Another is a localized lupus erythematosus-like reaction.^{313,314} Localized psoriasiform eruption and mucosal oral ulcerations have been recently reported in children treated for verruæ or molluscum contagiosum.³¹⁵

Bortezomib, a proteasome inhibitor used in the treatment of multiple myeloma, produces cutaneous reactions in at least 10% of patients.³¹⁶ Injection site reactions are common.³¹⁷ Erythematous nodules are commonly seen.³¹⁸ There was an interface dermatitis on histology, but there were only a few eosinophils in the superficial perivascular infiltrate.³¹⁶

The various reactions to cytotoxic drugs have been reviewed by Fitzpatrick³¹⁹ and by Susser and colleagues.³²⁰ A more recent review appeared in 2008.³²¹ The various toxic erythemas of chemotherapy were also reviewed in 2008.³²² Table 20.3 lists some distinctive reactions to newer chemotherapeutic agents and recombinant cytokines.

Recombinant cytokines

As a result of advances in recombinant DNA technology, recombinant cytokines are being used increasingly as therapeutic agents. An excel-

Table 20.3 Distinctive reactions to newer chemotherapeutic agents		
Class and agent	Clinical features	Microscopic changes/mechanism
Signal transduction inhibitors		
EGFR inhibitors		
Gefitinib, erlotinib, cetuximab	Papulopustular eruption	Suppurative folliculitis with granulomas, perifollicular T cells
	Xerosis	Thin, compact epidermis; variable parakeratosis
Cetuximab	Long, thick chest hair with folliculitis	Disoriented, shortened follicles with irregular keratinocyte architecture
Multikinase inhibitors		
Imatinib	Hypopigmentation or depigmentation	May be due to inhibition of c-kit
Dasatinib	Painful erythematous nodules	Lobular panniculitis; massive infiltration by neutrophils
Sorafenib, sunitinib	Acral erythema	Hypogranulosis, parakeratosis, enlarged and dyskeratotic keratinocytes
Spindle inhibitors		
Docetaxel	Acral erythema or hand–foot syndrome, fixed erythrodysesthesia plaque Scleroderma-like changes	Lichenoid dermatitis with mild spongiosis, sparse superficial perivascular infiltrate Dermal sclerosis, thickening of SQ septa (also seen with bleomycin)
Antimetabolites		
Gemcitabine	Scleroderma-like changes Pseudolymphoma	Dermal and SQ sclerosis Resembles lymphomatoid papulosis; widespread infiltrate of CD30 ⁺ cells

lent review of this subject and the cutaneous reactions to this therapy was provided by Asnis and Gaspari in 1995.¹⁷⁰ Some of these products are listed in Table 20.4.

Cutaneous reactions are more common with *granulocyte-macrophage colony-stimulating factor* (GM-CSF) than with *granulocyte colony-stimulating factor* (G-CSF). Reactions reported with G-CSF include Sweet’s syndrome, bullous pyoderma gangrenosum, acute vasculitis, and an exacerbation of psoriasis.^{323,324} There are several reports describing the presence of numerous enlarged, plump macrophages in the dermal infiltrate of some eruptions.^{325–328} Enlarged macrophages may also occur as a consequence of chemotherapy alone.²⁶⁰ Irregularly shaped lymphocytes, with some mitoses, may also be found in some of these eruptions.³²⁹ In the case of GM-CSF, reported complications include widespread folliculitis, bullous pyoderma gangrenosum, a psoriasiform eruption, erythroderma, and localized injection site reactions.^{170,330,331}

Erythropoietin, used in the treatment of anemia of chronic renal failure, produces few reactions; they include hirsutism and a spongiotic reaction. A lichenoid, focally granulomatous reaction was present in one patient who presented with erythroderma.³³²

The *interferons* may produce injection site reactions, particularly IFN-β. Reactions include erythema, localized induration, and necrosis,

Table 20.4 Recombinant cytokines, other antibodies, and inhibitors

Colony-stimulating factors	
Filgrastim Pegfilgrastim	} Granulocyte colony-stimulating factor
Sargramostin	Granulocyte–macrophage colony-stimulating factor
Erythropoietin	
Epoetin α	Produced by cultured Chinese hamster ovary cells, implanted with human epoietin gene using recombinant DNA techniques
Interleukins	
Aldesleukin	Recombinant human interleukin-2 (IL-2)
Anakinra	Recombinant form of human IL-1 receptor antagonist, preventing IL-1 signaling
Mepolizumab	Humanized anti-IL-5 monoclonal antibody
Interleukin-10	Experimental use only
Tumor necrosis factor- α (TNF- α) antagonists	
Infliximab	Chimeric monoclonal antibody to TNF- α
Etanercept	Recombinant TNF- α soluble receptor fused to Fc fragment of IgG ₁
Adalimumab	Recombinant human IgG monoclonal antibody specific for TNF- α
Lenalidomide Thalidomide	} Antagonists of TNF- α , but not recombinant
Epidermal growth factor receptor (EGFR) inhibitors	
Erlotinib	Inhibits the EGFR tyrosine kinase, similar to gefitinib
Gefitinib	Inhibits the activation of EGFR tyrosine kinase through competitive binding of the receptor
Cetuximab	Humanized antibodies that bind to the extracellular domain of EGFR
Panitumumab	Similar to above
Vascular endothelial growth factor (VEGF) inhibitor	
Bevacizumab	Monoclonal antibody against VEGF
Inhibitors of various kinases	
Sorafenib	Blocks a multitude of kinases, platelet-derived growth factor receptor, vascular endothelial growth factor receptor 2 and 3; blocks downstream pathways of EGFR; used for renal cell carcinoma
Sunitinib	Oral multikinase phosphorylation inhibitor of receptor tyrosine kinases
Imatinib	Inhibitor of BCR-ABL tyrosine kinase, found in Philadelphia chromosome positive leukemias, and used in its treatment
Monoclonal antibodies	
Rituximab	Monoclonal antibody to CD20
Ipilimumab Tremelimumab	} Monoclonal antibody to cytotoxic T-lymphocyte antigen 4 (CTLA4)
Efalizumab	Human monoclonal antibody to CD11a
Trastuzumab (Herceptin)	Humanized IgG ₁ murine antibody to the extracellular portion of the Her-2/neu receptor (HER2 antagonist)
Inhibitors and ligands	
Tipifarnib	Farnesyl-transferase inhibitor (targets Ras and other proteins)
Sirolimus (rapamycin)	mTOR inhibitor
Imiquimod	Toll-like receptor-7 agonist
Rosiglitazone	Peroxisome proliferator-activated receptor (PPAR) ligand
COL-3	Inhibitor of matrix metalloproteinases
Balicatib	Cathepsin K inhibitor
Octreotide	Insulin growth factor-I antagonist

often with associated thrombosis.^{333,334} Fibrosis often follows the necrosis.³³⁵ Mucinosis was associated with abdominal wall ulceration in one case.³³⁶ A squamous cell carcinoma has been reported in one of many ulcers that developed in a patient following the injection of IFN- β .³³⁷ If IFN- γ is used in the treatment of lepromatous leprosy, there is a high incidence of erythema nodosum leprosum. Alopecia is the most

common side effect of IFN- α . Other reactions include an eczema-like eruption, sometimes associated with photosensitivity, and pruritic plaques.³³⁸ A granulomatous and suppurative dermatitis can occur at injection sites.³³⁹ Cutaneous necrosis is another injection site reaction when pegylated IFN- α -2b is combined with ribavirin for the treatment of hepatitis C.³⁴⁰

Interleukin-2 therapy has resulted in bullous disorders and erythema nodosum. An erythematous macular eruption, healing with desquamation, is very common. Other reactions include erythroderma, telogen effluvium, cutaneous ulcers, exacerbation of psoriasis, and a persistent inflammatory reaction at the injection site.³⁴¹ A sclerodermoid reaction has also been produced.³⁴² *Interleukin-3* use has been associated with an urticarial eruption.³⁴³ *Anakinra*, an IL-1 receptor antagonist used in the treatment of rheumatoid arthritis, produces well-defined erythema and edema at injection sites. Biopsy specimens show a lichenoid infiltrate with many eosinophils and large CD68⁺ dermal macrophages, and mast cells.³⁴⁴ The appearances resemble those seen with G-CSF and GM-CSF (discussed previously). *Interleukin-10* plays a role in cutaneous infections and in autoimmune and neoplastic processes.³⁴⁵ Clinical trials of IL-10 have not given sustained benefit.

Tumor necrosis factor- α , an important proinflammatory cytokine, produces a generalized erythematous eruption, vasculitis, alopecia, and local reactions at the injection site.¹⁷⁰ *Inhibitors of TNF- α* (see [Table 20.4](#)) are used to treat several dermatological conditions.³⁴⁶ Etanercept, a recombinant TNF- α soluble receptor fused to the Fc fragment of IgG₂, produces injection site reactions in approximately 20% of patients, usually within the first 2 months of therapy.³⁴⁷ Eosinophilic cellulitis is a rare injection site reaction.³⁴⁸ Immediate type I hypersensitivity reactions are involved in some of the injection site reactions produced by adalimumab.³⁴⁹ Recall injection site reactions also occur.³⁵⁰ Systemic reactions also develop with etanercept and include leukocytoclastic vasculitis; eosinophilic vasculitis; eczematous, psoriasiform, and erythematous reactions; discoid lupus erythematosus; interstitial granulomatous dermatitis; and urticarial reactions.^{351–354} The onset of multiple squamous cell carcinomas has been reported during etanercept therapy.³⁵⁵ Various infections have followed the use of TNF- α antagonists. They include atypical (nontuberculous) mycobacterial infection, candidiasis, aspergillosis, cryptococcosis, coccidioidomycosis, and CMV infection.^{356,357} An atypical varicella exanthem has been reported with the use of infliximab.³⁵⁸ Hypertriglyceridemia has developed during treatment with adalimumab.³⁵⁹

Various skin reactions have resulted from the use of selective *epidermal growth receptor (EGFR) inhibitors* such as erlotinib and gefitinib used in the treatment of solid tumors, including non-small-cell lung cancer.^{360,361} Cetuximab and panitumumab are two further drugs in this class.³⁶¹ Side effects include annular eruptions, pustules,³⁶² paronychia, xerosis,³⁶⁰ the growth of terminal hairs on the nose tip,³⁶³ acneiform eruptions,^{364–367} a purpuric eruption,^{368,369} and erythroderma.³⁷⁰ Various nail changes have also been reported.³⁷¹

Inhibitors of various kinases, particularly tyrosine kinase (see [Table 20.4](#)), have been developed to treat various malignancies. Imatinib, an inhibitor of the tyrosine kinase encoded by the fusion gene *BCR-ABL* resulting from a translocation between chromosomes 9 and 22 in hematopoietic cells, is a frequent cause of adverse cutaneous reactions. They are generally of moderate severity and dose dependent.³⁷² They include exanthematous and lichenoid reactions, vasculitis, panniculitis,³⁷³ Stevens–Johnson syndrome, acute generalized exanthematous pustulosis, palmoplantar erythrodysesthesia,^{374,375} and neutrophilic eccrine hidradenitis.³⁷² A mycosis fungoides-like reaction has also been produced.¹⁵³ Sorafenib, a multikinase inhibitor, induces frequent cutaneous adverse events that include a hand–foot skin reaction, facial erythema, scalp dysesthesia, alopecia, and subungual splinter hemorrhages.³⁷⁶

A brief summary of cutaneous reactions to selected recombinant cytokines is provided in [Table 20.3](#).

Intravenous immunoglobulin

High-dose intravenous immunoglobulin therapy (hdIVIg) has been used to treat various diseases, including immunodeficiency states, autoimmune diseases, and hematological disorders. Adverse cutaneous

reactions are uncommon and include reports of eczema, alopecia, erythema multiforme, and a lichenoid dermatitis.^{377,378} Fifteen patients receiving intravenous immunoglobulin for inflammatory or demyelinating neuropathies developed erythema and desquamation, either generalized or primarily involving the palms. Microscopic changes were described as ‘dermatitis’, with spongiotic and urticarial features or featuring superficial perivascular inflammation.³⁷⁹

Monoclonal antibodies

Rituximab is a monoclonal antibody that specifically binds to the CD20 antigen. Although usually well tolerated, its systemic administration has been associated with a cytokine-release syndrome consisting of fever, chills, and stiffness during the first infusion.³⁸⁰ Cutaneous infusion reactions include urticaria, pruritus or burning sensation, or erythematous ‘rash’, especially in the head and neck region or on the chest.³⁸¹ Late-onset neutropenia is another complication.³⁸²

Efalizumab is a monoclonal antibody that binds to the CD11a subunit of lymphocyte function-associated antigen 1 (LFA-1), blocking its interaction with ICAM-1. As such, it interferes with many steps in the immune cascade involved in the pathogenesis of psoriasis, and it is used in its treatment.³⁸³ However, new papular lesions of psoriasis can appear during treatment of the original psoriasis.³⁸³ Plantar exfoliation and desquamation may also follow its use.³⁸⁴

Ipilimumab, a monoclonal antibody to cytotoxic T-lymphocyte antigen 4 (CTLA4), has been used to treat patients with metastatic melanoma.³⁸⁵ It has a high incidence of cutaneous reactions, including vitiligo, alopecia, and intertriginous eruptions.³⁸⁵

Vemurafenib is also a monoclonal antibody to CTLA4, and it is a potent kinase inhibitor with specificity for the BRAF V600 E mutation; thus, it has a major role in the treatment of metastatic melanoma. ‘Rash’, photosensitivity reactions, pruritus, cutaneous papillomas, and cutaneous squamous cell carcinomas or keratoacanthomas have been reported in more than 25% of patients. The latter two lesions tend to appear early in the course of treatment, are eruptive and fast growing, but are generally well differentiated and not prone to metastasis.³⁸⁶

Protease inhibitors

As mentioned previously, patients infected with HIV have a higher incidence of drug hypersensitivity than individuals with normal immunity. Protease inhibitors have been used for several years in the treatment of HIV infection, often with dramatic effects on both the viral load and CD4 cell count. Adverse cutaneous reactions to protease inhibitors include a lipodystrophy (see p. 545),³⁸⁷ a maculopapular eruption,³⁸⁸ stria formation, and excess granulation tissue of the digits with paronychia.³⁸⁹ Indinavir has the greatest number of documented cutaneous reactions, including acute porphyria, Stevens–Johnson syndrome, venous thrombosis, and ‘frozen shoulder’.³⁹⁰

Botulinum toxin

Adverse events are very uncommon with botulinum toxin type A (Botox[®]) considering its widespread use in the treatment of wrinkles.³⁹¹ Deaths have been reported from its therapeutic as opposed to its cosmetic usage, probably because of the higher doses used, but it is likely that most of these were fortuitous associations. Injection site reactions are most common and include edema, pain, bruising, and a ‘rash’. An allergic, more generalized, rash has also been reported.³⁹¹

INTRODUCTION

Various physical agents, such as trauma, heat and cold, radiation, and light, may cause lesions in the skin.¹ This is not an exhaustive account of all the reactions that can theoretically result from physical injuries, as some are of little dermatopathological importance. Several entities produced by physical agents have been discussed in other chapters because they possess a distinctive histopathological pattern. For completeness, brief mention is made of these entities in the introductory discussion to the relevant physical agent.

REACTIONS TO TRAUMA AND IRRITATION

There are many cutaneous lesions that result from trauma and irritation in the broadest meaning of the words.² However, some of these, such as abrasions, bruises, and lacerations,^{3,4} are of no dermatopathological interest; animal and human bites also belong to this category.⁵ In contrast, calcaneal petechiae ('black heel') and related traumatic hemorrhages in some other sites are important because they are sometimes mistaken clinically for a melanocytic lesion. Dermatitis artefacta is also an important entity because its clinical recognition is often delayed. Many quite diverse lesions can result, particularly when foreign materials are injected into the skin.

Entities discussed in other sections include scars (see p. 365), corns and calluses (see p. 827), and acanthoma fissuratum, a reaction to chronic friction from ill-fitting spectacles or other prostheses. Granuloma fissuratum presents with irregular acanthosis bordering on pseudoepitheliomatous hyperplasia and is accordingly discussed with that tissue reaction pattern on page 787.

Traumatic lesions are now being seen from a diverse group of agents. They include air bags in cars,^{6,7} cupping, resulting from a localized vacuum applied against the skin and used in Asia as an alternative therapy for a variety of ailments,⁸ and torture.⁹ Prayer marks are sometimes seen on the foreheads and knees in Muslims who pray for prolonged periods.¹⁰ Skin thickening, lichenification, and hyperpigmentation are the important consequences.¹⁰

DERMATITIS ARTEFACTA

Dermatitis artefacta is a self-inflicted dermatosis occurring in malingerers, the mentally handicapped, and in association with various psychiatric disturbances, particularly personality disorders.^{11,12} The definition is sometimes extended to include factitious lesions resulting from child abuse.^{13,14} Two reviews of the cutaneous manifestations of child abuse have been published.^{15,16} Abuse by burning comprises approximately 6–20% of all child abuse cases.^{16,17} Ecchymoses and bruising are further signs suspicious for abuse.¹⁶

Dermatitis artefacta may take many different forms, depending on the injurious agent used.^{11,18–21} Crusted erosions, ulcers, keloids, scars, psoriasis-like lesions, chemical and thermal burns, and changes resulting from hair cutting and shaving are among the many lesions encountered.^{22–30} Rarely, it may masquerade as pyoderma gangrenosum.³¹ In younger persons, more than 50% of the lesions are on the head and neck.^{24,26} Bullous lesions on the lower legs were reported in an adolescent, but the mechanism of their production was never elucidated.³² Bullae have also followed the use of deodorant spray applied close to the skin for 100 seconds.³³ The distribution and shape of these various lesions may be bizarre, sometimes having linear or geometric outlines.³⁴ Usually, there are lesions in different stages of evolution. Deep abscesses, cellulitis, lipogranulomas, and other granulomatous lesions may result from the injection of various substances.³⁵ At times,

cutaneous manifestations of systemic diseases can mimic dermatitis artefacta; an example is the excoriated nodules on both arms that occurred in a patient with Epstein–Barr virus-positive subcutaneous panniculitis-like T-cell lymphoma.³⁶

It has been proposed that some ulcerations in patients with reflex sympathetic dystrophy may be of factitial origin.³⁷

The terms dermatitis neglecta, 'terra firma-forme' dermatosis, and keratoderma simplex³⁸ have been used for acquired, asymptomatic plaques, often on the neck, resembling a pigmented lesion, a verrucous nevus, or acanthosis nigricans. They rub off with alcohol (see p. 343).³⁹

A review of the clinical features, diagnosis, and treatment of dermatitis artefacta has recently been published.⁴⁰

Histopathology

A diagnosis of dermatitis artefacta is not often made in the absence of supporting evidence from the clinician. The reasons for this include the lack of histopathological specificity in most instances, the medico-legal implications of making such a diagnosis, and the traditional fear among doctors of missing an organic disease.⁴¹

There is little limit to the type of lesion that may be found: they may take the form of abrasions, excoriations, ulcers, and burns. There may be abscesses, cellulitis, suppurative panniculitis, irritant and allergic contact dermatitis, alopecia (trichotillomania), or hemorrhage. In the presence of granulomas or abscesses, a search should always be made for foreign material, including an examination for doubly refractile particles. Electron-probe microanalysis may assist in the identification of foreign material found in tissue sections.⁴² The previously mentioned case of bullous dermatitis due to deodorant spray showed a subepidermal blister with necrosis of the overlying epidermis and a superficial dermal infiltrate composed of lymphocytes and lacking eosinophils.³³

Telangiectasia of vessels in the dermis has been reported as a response to persistent local trauma, although in the cases reported, the trauma was not intentional but resulted from recreational pursuits.⁴³

DECUBITUS ULCER

Decubitus ulcers (bedsores) are a worldwide health care problem affecting tens of thousands of patients.⁴⁴ They usually develop over pressure areas such as the sacrum, the greater trochanter, and the heels, usually in individuals confined to bed for long periods.^{45–48} Prolonged pressure is thought to compromise the vascular supply of the affected areas, although the pathogenic steps leading to ulceration have not been investigated in detail.^{49,50} Several clinical stages have been identified, including a preceding erythematous stage and a late stage in which a black eschar forms.⁵¹ In the United States, the National Pressure Ulcer Advisory Panel has established an updated pressure ulcer staging system. This four-stage system includes the following: stage I – nonblanchable erythema with no tissue loss; stage II – partial-thickness ulcer with skin breakdown but minimal tissue necrosis; stage III – full-thickness ulceration with breakdown extending through the dermis to expose subcutaneous tissue; and stage IV – extension of the process through deep fascia, with damage to underlying muscle and bone.^{52,53} Necrotizing fasciitis due to group B *Streptococcus* has been reported as a complication of decubitus ulcer.⁵⁴

Uncommonly, a cutaneous metastasis may mimic a decubitus ulcer.⁵⁵ In addition, there are reports of perforated ischiogluteal bursitis in patients with spinal cord injury, which can mimic decubitus ulcer. Treatments for this uncommon condition require resection of the bursa, with the sometimes necessary addition of musculocutaneous flap surgery to provide appropriate cushioning.⁵⁶

Pressure ulcers are difficult to treat, so prevention is an important strategy. The main treatment principles include reduction of pressure, friction, and shear forces; local wound care; surgical debridement of

necrotic tissue; and management of any secondary infection.⁵⁷ A randomized trial found that traditional resin salve is significantly more effective in the treatment of severe pressure ulcers than cellulose polymer gauzes.⁵⁷ An allogeneic platelet leukocyte gel has been used successfully in treating an occipital decubitus ulcer in a neonate.⁵⁸

Histopathology⁵¹

The earliest changes are in the upper dermis, where the vessels become dilated and the endothelial cells swollen. A perivascular round cell infiltrate forms in the papillary dermis together with vascular engorgement, formation of platelet aggregates, and perivascular hemorrhage. Mast cells are increased in number.⁵⁹ The epidermis and appendages become necrotic. If the process is acute, a subepidermal bulla forms prior to epidermal necrosis. There is abundant fibrin.⁶⁰ In some cases of low-grade, chronic pressure, epidermal atrophy will result. Full-thickness dermal necrosis with the formation of an eschar may develop where the skin is thin and bony prominences are close to the surface.⁵¹ Re-epithelialization is always very slow when the epidermis and appendages have both been destroyed and there is endarteritis of small arteries; grafting is usually required.

Atypical decubital fibroplasia (alternatively termed *ischemic fasciitis*) is a pseudosarcomatous proliferation of cells with fibrinoid necrosis, reactive fibrosis, and fat necrosis (see p. 978).

FRICION BLISTERS

Friction blisters are produced at sites where the epidermis is thick and firmly attached to the underlying dermis, such as the palms, soles, heels, and back of the fingers.^{61,62} A common site is the heel, where blisters are caused by ill-fitting footwear.⁶³ Friction blisters are an uncommon manifestation of dermatitis artefacta.⁶¹ If the trauma is prolonged and severe or the skin is thin, erosions will occur. Recovery is rapid and complete within a few days.⁶⁴

Histopathology⁶¹

There is an intraepidermal blister due to a wide cleft that is usually just beneath the stratum granulosum. The roof of the blister consists of stratum corneum and stratum granulosum and a thin layer of amorphous cellular debris.⁶⁵ The keratinocytes in the base of the blister show variable edema, pallor, and even degenerative changes.⁶⁶ There is only a sparse perivascular inflammatory cell infiltrate in the papillary dermis. Friction blisters differ from suction blisters, which are subepidermal in position.⁶⁷

Mitotic activity commences in the base within 30 hours, and there is rapid regeneration with the return of a granular layer in 48 hours.⁶⁴

Electron microscopy⁶⁸

The earliest change is intracellular edema, most noticeable at the cell periphery. The membranes of some cells rupture, allowing escape of some of their contents into the extracellular space.

CALCANEAL PETECHIAE ('BLACK HEEL', TALON NOIR)

'Black heel', which is usually bilateral and roughly symmetrical, consists of a painless, petechial eruption on the heels.^{63,69-71} There is speckled, brownish-black pigmentation that may be mistaken for a plantar wart or even a melanoma.⁷² It should not be forgotten that melanoma can occur on the heel.⁷³

Calcaneal petechiae appear to be traumatic in origin. Their formation probably follows a pinching force imparted by shoes at the time

of sudden stopping, such as occurs in the course of basketball, tennis, and other sports.^{72,74}

Lesions comparable in appearance, pathogenesis, and pathology occur in other situations.^{75,76} They include jogger's toenail,⁷⁷ weeder's thumb,⁷⁸ and PlayStation® thumb.⁷⁹ They may follow the wearing of new shoes or the pricking of a blister with a needle.⁸⁰ The term post-traumatic punctate hemorrhage has been proposed as a unifying term.⁷⁵ Subungual blood may also be the presenting sign of an underlying tumor of the nail bed.⁸¹ There are many causes of splinter hemorrhages of the nails. Trauma is the most common cause, but systemic illnesses, including cardiovascular, renal, and pulmonary diseases, are other etiological agents. Idiopathic cases also occur.⁸²

Subungual hemorrhage produced by acitretin has also been reported.⁸³

Histopathology^{71,84}

The pigmentation in calcaneal petechiae results from lakes of hemorrhage in the stratum corneum (Fig. 21.1). The red cells are extravasated into the lower epidermis from dilated vessels in the papillary dermis. They undergo transepidermal elimination during the progressive maturation of the epidermis and overlying stratum corneum.

Figure 21.1 Traumatic hemorrhage involving the stratum corneum. The lesion was removed because of a clinical suspicion that this was a melanoma. (H&E)

Red cells may also be found in the stratum corneum following trauma to the palms, soles, and subungual region. Hemorrhage also occurs into the parakeratotic layer overlying the digitate papillomatous projections in warts. The hemoglobin in these deposits can be demonstrated with either the benzedine stain or the patent blue V stain.⁸⁵

REACTIONS TO RADIATION

The early (acute) effects of X-irradiation differ markedly from those that develop many months or years later. In the skin, the terms 'acute radiodermatitis' and 'chronic radiodermatitis' have traditionally been used for these respective stages. A subacute form has also been described with features resembling those of acute graft-versus-host disease.⁸⁶ All three stages are discussed here under the general heading of radiation dermatitis.

The effects of *ultraviolet radiation* are quite different. Ultraviolet-B radiation (UVB) produces apoptosis of keratinocytes ('sunburn cells'), spongiosis, and eventual parakeratosis. Endothelial cells in the superficial vascular plexus enlarge, and there is some perivenular edema.⁸⁷ Langerhans cells in the epidermis are reduced in number for several days after the exposure. Ultraviolet-A radiation (UVA) produces only mild swelling of keratinocytes and mild spongiosis but no sunburn cells.⁸⁷ Exposure to ultraviolet radiation, both UVA and UVB, in commercial tanning salons has the potential to become a major public health problem in the future. Skin burns, which may predispose to the development of skin cancer later in life, have been reported in a significant number of users.⁸⁸

Radiofrequency energy is used in a catheter ablation technique for the treatment of a variety of cardiac arrhythmias. If the procedure is prolonged, a localized acute radiodermatitis may result.^{89,90} A tender or pruritic erythematous plaque develops several days later. Histologically, there are scattered apoptotic keratinocytes resembling a mild phototoxic dermatitis (see later). New collagen production is stimulated by radiofrequency-based devices designed to reduce cutaneous wrinkles.⁹¹ The changes are quite subtle.⁹¹

Nuclear accidents are fortunately quite rare. Neutron and gamma rays may be released in such circumstances.⁹² DNA breaks occur in the cells as a consequence of radiation exposure resulting in confluent apoptosis and necrosis of epidermal cells and involvement also of appendageal epithelium.⁹²

RADIATION DERMATITIS

There is a common response to the different types of radiation that affect the skin, although the severity of the changes varies with the total dose, its fractionation, and the depth of penetration of the radiation.⁹³⁻⁹⁵ The use of megavoltage therapy for deep tumors has resulted in some sparing of the skin, although fibrosis in the deep subcutaneous tissues may result.^{95,96}

The advent of coronary angioplasties and stenting has resulted in several cases of radiation dermatitis as a consequence of excessive radiation, usually associated with a prolonged fluoroscopy-guided procedure. Lesions are usually on the upper back.⁹⁷⁻⁹⁹ Presentations include a vascular lesion, a morphea-like lesion, skin necrosis, or an unexplained ulcer.⁹⁸⁻¹⁰⁰ As previously mentioned, radiofrequency energy used in various cardiac ablation techniques can also produce localized radiodermatitis.

There is a well-defined progression of changes following irradiation of the skin.⁹⁵ These are usually divided into early changes (acute radiodermatitis) and chronic changes (chronic radiodermatitis) arising many months or years after the initial exposure.^{101,102} An intermediate (subacute) stage is also recognized. The complications of ionizing radiation have been reviewed.¹⁰³

Early radiation dermatitis

In the weeks following irradiation, there is variable erythema, accompanied by edema in the more severe cases.⁹⁵ This is followed by epilation and hyperpigmentation. Severe changes, such as vesiculation, erosion, and ulceration, are not seen very often in these days of more precisely controlled dosage; they may occur after accidental exposures.¹⁰⁴ In the United States, the National Cancer Institute has produced a clinical grading system (1-4) for the manifestations of acute radiation dermatitis.¹⁰³

Vitamin E has no preventative effects on acute skin reactions, despite its experimental benefits in preventing carcinogenic effects in animals.¹⁰⁵ In contrast, topical corticosteroid therapy ameliorates acute radiation dermatitis.¹⁰⁶

Subacute radiation dermatitis

Subacute radiation dermatitis, which occurs weeks to months after radiation exposure, was first described in 1989 by LeBoit.⁸⁶ Further localized cases have been described as a consequence of radiation from fluoroscopy during coronary artery procedures.^{107,108} It is a histological imitator of acute cutaneous graft-versus-host disease (see later).^{86,107}

Eosinophilic, polymorphic, and pruritic eruption of radiotherapy (EPPER)

This complication of radiotherapy for cancer, particularly of the breast, has a unique clinicopathological profile. It has been diagnosed in the past as erythema multiforme and bullous pemphigoid following radiotherapy. It has received little attention in the literature, despite the ability of one institution to collect 14 cases.¹⁰⁹ The eruption is polymorphic and pruritic. The eruption usually occurs during irradiation, but late onset has been recorded.¹¹⁰ It is considered further with the spongiotic reaction pattern because this characterizes the histological pattern (see p. 108).

Late radiation changes

The chronic effects progress slowly and are usually subclinical in the early stages.⁹⁵ It seems that at least 1000 rads is required to produce chronic radiodermatitis.¹¹¹ The final changes resemble poikiloderma, with atrophy, telangiectasias, hypopigmentation with focal hyperpigmentation, and loss of appendages.¹¹² Similar changes have been observed in survivors of the Chernobyl nuclear power plant disaster, when reviewed 15 years later.¹¹³ Fluoroscopy-induced chronic radiation dermatitis has been associated with prolonged exposure during cardiac catheterization and other similar procedures.^{114,115} The location of the lesion correlates with the nature of the particular fluoroscopic procedure; thus, coronary procedures are associated with exposure to the region of the right scapula, cardiac radiofrequency ablation with the lateral back/axilla, and transjugular intrahepatic shunt placement with the back.¹¹⁵ The affected skin is very susceptible to minor trauma, which may lead to persistent ulceration.¹¹⁶

A small proportion of patients develop squamous^{117,118} or basal cell carcinoma 15 years or more after irradiation.^{119,120} Rarely, fibrosarcomas have been reported: their diagnosis might not stand up to scrutiny with the immunoperoxidase markers available today. Basal cell carcinomas are more common following irradiation to the head and neck region.¹²¹ Sometimes the tumors that develop are quite aggressive, and there is a higher risk of metastasis with any squamous cell carcinoma that develops in the skin following irradiation than with cutaneous squamous cell carcinoma in general.¹⁰² An absorbed dose of at least 2000 rads is required.¹²² The risk of cutaneous cancer following superficial grenz therapy is very small indeed.^{123,124}

Radiation recall dermatitis

Radiation recall dermatitis is the development of an inflammatory reaction in a previously irradiated field, precipitated by the administration of certain drugs, usually cytotoxic drugs administered intravenously,^{125–127} and including the newer agents sorafenib¹²⁸ and trastuzumab.¹²⁹ Other drugs associated with radiation recall dermatitis include azithromycin¹³⁰ and levofloxacin.¹³¹ A similar reaction has been induced by UV radiation in a patient who had previously received total body irradiation and chemotherapy.¹³²

Histopathology of radiation and radiation recall dermatitis⁹⁵

The *early changes* of radiation dermatitis are not commonly seen because there is usually little reason to perform a biopsy. There is some vacuolization of epidermal nuclei and cytoplasm with some degenerate keratinocytes. Inhibition of mitosis occurs in the germinal cells of the epidermis and pilosebaceous follicles. The follicles soon pass into the catagen phase. Later, there is hyperpigmentation of the basal layer. The blood vessels in the papillary dermis are dilated, and their endothelial cells are swollen. There is edema of the papillary dermis and extravasation of red blood cells and fibrin. Thrombi composed of fibrin and platelets may form in some vessels. Only a small number of inflammatory cells are present, and these are usually dispersed and not perivascular in location.

A recent study using reflectance confocal microscopy showed that histopathologic changes by this method can be discerned at an average of 15 days following therapy, whereas clinical features generally appear at approximately 30 days.¹³³ Common changes seen by this method initially include spongiosis and dermal inflammatory cells, followed by exocytosis, the appearance of dendritic cells, 'broken, geographic' dermal papillae, and epidermal linear cell arrangements of 'streaming-like' figures.¹³³

In *subacute radiation dermatitis*, there is a lichenoid tissue reaction (interface dermatitis) with basal vacuolar change, some cytologically atypical keratinocytes, and apoptotic keratinocytes (Fig. 21.2). Lymphocytes, which are predominantly CD8⁺ and express TIA-1, a cytotoxic granule protein in T cells, are found in a superficial perivascular location in the dermis and also in the epidermis in close apposition with apoptotic keratinocytes ('satellitosis'). There may be a fibrinopurulent crust on the epidermal surface.¹⁰⁷

Figure 21.2 Subacute radiation dermatitis. There is an interface dermatitis with some basal vacuolar change. (H&E)

In the *late stages*, the epidermis may be atrophic with loss of the normal rete ridge pattern and the development of focal basal vacuolar change. Sometimes there is overlying hyperkeratosis. Dyskeratotic cells are usually present. The main changes are in the dermis, where there is swollen, hyalinized collagen showing irregular eosinophilic staining (Fig. 21.3). This results from marked upregulation of collagen synthesis.¹³⁴ Atypical stellate cells with large nuclei containing clumped chromatin (radiation fibroblasts) are invariably present.¹³⁵ Most of these cells express factor XIIIa;^{136,137} a few express CD34.¹³⁶ There are telangiectatic vessels in the upper dermis with marked dilatation of their lumen and swelling of the endothelial cells. Vessels are generally reduced in number. Those near the dermal–subcutaneous junction may show varying degrees of myointimal proliferation. Small arterioles and venules often show hyaline change in their walls, with narrowing of the lumen.

Pilosebaceous structures are absent in late radiation changes, and there is some atrophy of eccrine sweat glands. The arrector pili muscles remain, in contrast to the changes following thermal burns, when they are lost. The surviving muscle fibers are often embedded in a pear-shaped mass of collagen, giving the appearance of a bulbous scar.

Less common findings include ulceration, secondary infection and inflammation, and dysplastic epidermal changes resembling an actinic keratosis. Basal or squamous cell carcinomas may supervene. The deep subcutaneous fibrosis that may follow megavoltage therapy overlies atrophic and degenerated skeletal muscle fibers.⁹⁶

In *radiation recall dermatitis*, the changes are indistinguishable from deep radiation dermatitis, panniculitis, and myositis.¹²⁵ There is a diffusely fibrosclerosing process, involving deep dermis, the subcutis, and the underlying muscle,¹²⁵ sometimes including radiation fibroblasts.¹³⁸

Differential diagnosis

The interface changes seen in subacute radiation dermatitis can closely mimic graft-versus-host disease. As noted by LeBoit, cytologic atypia is not in itself a feature of graft-versus-host disease but could be seen in that disorder when combined with chemotherapy effects. In addition, lymphocytic infiltrates can be moderately dense in subacute radiation dermatitis, which can overlap with the findings in acute graft-versus-host disease. Clinical correlation is therefore essential in these cases. Numerous conditions are characterized by sclerosis of dermal collagen and could therefore be confused with chronic radiation dermatitis; examples include morphea/scleroderma and scars resulting from causes other than radiation, such as thermal injury. However, the large, atypical radiation fibroblasts are quite characteristic of chronic radiation injury. In addition, arrector pili muscles and (often) eccrine sweat glands are preserved in chronic radiation dermatitis, whereas these structures are destroyed in deep thermal burns. Eosinophilic, polymorphic, and pruritic eruption is often a surprising finding in the context of prior irradiation therapy. The differential diagnosis includes other causes of eosinophilic dermatitis and panniculitis, such as reaction to drug or arthropod, Wells' syndrome, the eosinophilic panniculitis that clinically mimics erythema nodosum, injection therapies, vasculitis with eosinophils, or lymphoproliferative disorders.

REACTIONS TO HEAT AND COLD

There are two broad groups of temperature-dependent skin disorders.¹³⁹ The first involves the physiological responses that occur in everyone subjected to extremes of temperature. This group includes thermal burns and cold-related disorders such as frostbite. The other group of disorders involves an abnormal response to heat and cold. Abnormal reactions to heat include erythema ab igne (see p. 395), cholinergic urticaria (see p. 228), heat urticaria (see p. 228), and erythromalgia.¹³⁹ There are numerous abnormal reactions to cold, such as perniosis (see p. 267), livedo reticularis, cold urticaria (see p. 228),

Figure 21.3 Radiation damage. (A) There is loss of dermal appendages. Blood vessels are telangiectatic. (B) The dermal collagen is altered with several 'radiation fibroblasts' (dendrocytes). (H&E)

sclerema neonatorum (see p. 538), subcutaneous fat necrosis of the newborn (see p. 537), Raynaud's phenomenon (see p. 348), and cryoglobulinemia (see p. 224).¹³⁹

The following reactions to heat and cold are considered further:

- Thermal burns
- Electrical burns
- Frostbite
- Cryotherapy effects
- Polymorphous cold eruption.

THERMAL BURNS

Thermal burns are an important cause of morbidity and mortality. In children, most burns are scalds from hot liquids, whereas in adults accidents with flammable liquids are more common.^{140–143} Burns are sometimes a manifestation of child abuse.¹⁴⁴ Acute lesions have traditionally been classified into first-, second-, and third-degree burns according to the extent of the damage.¹⁴⁵ However, some surgeons categorize burns into superficial and deep types. Unfortunately, even this simple classification is difficult to apply on the basis of physical findings alone.¹⁴⁶ A common but neglected phenomenon is the occurrence of blisters weeks to months following a burn, after initial successful healing of partial-thickness wounds. This 'delayed postburn blister' may occur for up to 12 months or more after injury.¹⁴⁷ Its mechanism is unknown, but it may be due to shearing forces in an area with reduced numbers of anchoring fibrils.¹⁴⁷

Secondary infections, usually due to gram-negative bacteria, are an important complication in the acute stage. Alopecia may follow a deep burn to the scalp.¹⁴⁸ A late complication, occurring 20–40 years later, is the development of a squamous cell carcinoma.^{149,150} These tumors have a higher risk of metastasis than the usual squamous cell carcinomas of the skin.¹⁵¹ Basal cell carcinomas and, rarely, malignant fibrous histiocytomas or malignant melanomas may likewise develop many years after the injury.^{152–155} Dystrophic xanthomatosis is another rare complication (see p. 1161). In a recently reported case, a woman developed cutaneous lupus erythematosus, actinic keratoses, and squamous cell carcinoma at the site of a burn injury to the face that had occurred 40 years previously; the authors believe that this supports the concept of an 'immunocompromised district' at the site of injury.¹⁵⁶

Histopathology¹⁵⁷

Biopsy may be of assistance in evaluating the extent of the lesion and the presence of secondary infection, particularly if this is due to a fungus (e.g., *Aspergillus* or *Mucor*) or virus. It should be kept in mind that it may be difficult to assess the depth of dermal damage in the first 24 hours because the changes in the collagen are not always fully developed.

In first-degree burns, there may be necrosis involving the upper part of the epidermis. Second-degree burns, also known as partial-thickness injury, vary greatly in their extent (Fig. 21.4). In superficial variants, there is necrosis of the epidermis with an exudative crust of fibrin, neutrophils, and epithelial cellular debris. Vertical elongation of epidermal keratinocytes usually occurs. Subepidermal blisters may also form. Dermal damage is mild and superficial, and there is only a sparse inflammatory cell infiltrate. In deep second-degree burns, many of the pilosebaceous appendages are destroyed, together with much of the dermal collagen. There is fusion of collagen bundles, which show a refractile eosinophilic appearance. Similar changes may occur in vessel walls, and there may be thrombosis. Granulation tissue forms at the interface between damaged and viable tissues, resulting in scarring. Epidermal regeneration develops from surviving epithelial components, particularly the eccrine glands, which undergo squamous metaplasia.

Figure 21.4 Thermal burn. The dermal collagen is 'homogeneous'. The epidermis is necrotic, and there is focal subepidermal clefting. (H&E)

Figure 21.5 Electrical burn. There is subepidermal separation with elongated cytoplasmic processes and homogenization of upper dermal collagen. (H&E)

In full-thickness (third-degree) burns, the necrosis involves the entire thickness of the skin, including variable amounts of underlying fat. An inflammatory exudate forms at the junction of the viable and nonviable tissue, and granulation tissue eventually forms. The necrotic eschar separates after approximately 3 weeks. Because appendages have been destroyed, the only re-epithelialization that can occur is at the margins or by the application of a skin graft.

The scar that follows deep second-degree and third-degree burns is composed of hyalinized collagen. There is usually a decrease in the elastic fibers. Arrector pili muscles are generally lost, in contrast to their preservation in cases of chronic radiation damage, in which they become embedded in scar tissue (see p. 614).¹⁵⁸

The delayed postburn blister that sometimes forms after initial healing is subepidermal in type.¹⁴⁷ There are no immune deposits.

ELECTRICAL BURNS

In the United States, the overall incidence of all burns is approximately 4/1000 per year, but only 3% occur as a result of electrical injury.¹⁵⁹ Electrical burns may be of variable severity, depending on the nature of the current, the voltage, and the extent of contact with the

skin. They resemble third-degree thermal burns, although in severe electrical burns there is deep vascular damage leading to cutaneous infarcts that are slow to heal.^{145,160} Electrical burns in the mouth result in irregularly shaped ulcers covered by slough.¹⁶¹ Third-degree burns have been incurred as a result of interferential current therapy used to treat pain and reduce edema.¹⁵⁹

Lightning strikes may be associated with full-thickness burns, linear charring, and branching or ferning marks known as Lichtenberg figures.^{162,163}

Histopathology

The use of controlled electrical currents during diathermy and electrodesiccation produces epidermal necrosis resembling thermal burns. A similar picture results from the use of short-pulse, carbon dioxide laser.¹⁶⁴ Based on animal experiments, it seems that the energy required to vaporize the dermis is greater than that needed for the epidermis.¹⁶⁵ In electrical burns, elongated cytoplasmic processes extrude from the basal cells into the cavity that forms by dermoepidermal separation. More superficial keratinocytes in the epidermis may also show vertical elongation. There is also homogenization of the collagen in the upper dermis (Fig. 21.5). In severe electrical burns, there is infarction of the

entire thickness of the dermis and subcutis, with necrosis of vessel walls in the deeper tissue.¹⁶⁰ Hemorrhage often accompanies this vessel damage.¹⁶⁰

The Lichtenberg figures seen following lightning strikes show subcutaneous hemorrhage.¹⁶²

FROSTBITE

Frostbite occurs when tissue freezes.¹³⁹ Usually, an acral part, such as a finger, toe, ear, or even the nose, is involved. The affected part becomes white or bluish white.¹³⁹ A blister forms a day or so after rewarming, and this is followed some days later by the formation of a hard eschar.¹³⁹ Autoamputation of the affected area eventually occurs. The terms ‘chilblain’ and ‘perniosis’ (see p. 267) are used for a specific lesion that may result from exposure to cold temperatures.

Cold injury has resulted from electronic cooling devices attached to the knee after knee surgery in an attempt to decrease postoperative pain and inflammation.¹⁶⁶ The histological changes were similar to those seen in perniosis.¹⁶⁶ Skin changes clinically identical to those of frostbite have been described as a rare manifestation of Isaacs’ syndrome, a potassium channel disorder in which there are autoantibodies directed toward VGKC (voltage-gated potassium channel), a dendrotoxin-sensitive fast potassium channel.¹⁶⁷ This leads to hyperexcitability of peripheral nerves and is generally associated with muscle cramps and slow relaxation after muscle contraction.¹⁶⁷

Histopathology

The affected area is necrotic, and an inflammatory infiltrate is found at the periphery. Granulation tissue eventually forms at the junction between viable and necrotic tissue.

CRYOTHERAPY EFFECTS

Cryotherapy using carbon dioxide or liquid nitrogen is commonly used in the treatment of cutaneous tumors and premalignant keratoses. Because cryotherapy involves rapid cooling, it produces numerous intracellular ice crystals and hence more destruction than does the slow cooling of an area.¹³⁹

The effects of cryotherapy on normal skin have been elucidated using volunteers and by studying the skin adjacent to lesions that are removed subsequent to cryotherapy. These studies have shown that different cells vary in their susceptibility to cold injury.¹³⁹ For example, melanocytes appear to be particularly sensitive to the effects of cold – an explanation for the hypopigmentation that may follow cryotherapy.

Histopathology¹⁶⁸

The application of liquid nitrogen results in the loss of cellular outline in the epidermis, which appears homogenized. The upper dermis becomes edematous, and a subepidermal bulla forms (Fig. 21.6). If the application is more prolonged, homogenization of the upper dermis also occurs. Similar changes occur in any tumor that is so treated.

New collagen is laid down in the papillary dermis over several weeks, and this may be accompanied by blunting of the rete pegs. Sometimes excessive collagen forms, leading to scarring. In solar elastotic skin, new collagen fibers are often intermingled with elastotic fibers.¹⁶⁹ There may be small foci of giant cell elastoclasia, with multinucleate foreign body giant cells phagocytosing a few of the elastotic fibers.¹⁶⁹ Focal acanthosis or pseudoepitheliomatous hyperplasia may develop, often in relation to the transepidermal elimination of damaged collagen and elastic fibers.¹⁶⁹ These changes may lead to a

Figure 21.6 Cryotherapy blister. The lesion is subepidermal with luminal hemorrhage. (H&E)

clinical suspicion that the initial lesion has not responded to the cryotherapy.

Another change that follows cryotherapy is localized hypopigmentation, sometimes with a halo of hyperpigmentation.¹⁷⁰ In either case, there may be some melanin lying free, or in macrophages, in the upper dermis.

POLYMORPHOUS COLD ERUPTION

Polymorphous cold eruption – a rare, autosomal dominant disorder – is characterized by a nonpruritic erythematous eruption developing after generalized exposure to cold air.¹⁷¹ The lesions are usually localized to the face and extremities. The eruption is often accompanied by fever, malaise, and headache. It differs clinically and histologically from cold urticaria, with which it is often confused.

Histopathology¹⁷¹

There is a superficial and deep mixed inflammatory cell infiltrate composed of lymphocytes, neutrophils, and eosinophils. An infiltrate

composed predominantly of neutrophils is present around eccrine sweat glands. There is no vasculitis.

REACTIONS TO LIGHT (PHOTODERMATOSES)

The photodermatoses are a heterogeneous group of cutaneous disorders in which light plays a significant pathogenetic role.^{172,173} This group is sometimes expanded by the inclusion of those conditions, both congenital and acquired, that are exacerbated in some way by light but that are not directly produced by it.^{174–179} This expanded concept of light-sensitive dermatoses includes the following diseases:

- **Genodermatoses**
 - Xeroderma pigmentosum
 - Cockayne's syndrome
 - Bloom's syndrome
 - Hartnup disease
 - Rothmund–Thomson syndrome
 - Smith–Lemli–Opitz syndrome^{180–183}
 - Kindler's syndrome
- **Metabolic/nutritional dermatoses**
 - Porphyria
 - Disorders of tryptophan metabolism
 - Pellagra
- **Light-sensitive dermatoses**
 - Lupus erythematosus
 - Lichen planus variants
 - Rosacea
 - Hailey–Hailey disease
 - Darier's disease
 - Seborrheic dermatitis
 - Atopic dermatitis
 - Erythema multiforme
 - Pityriasis rubra pilaris
 - Disseminated actinic porokeratosis
 - Herpes simplex infections
- **Photodermatoses**
 - Phototoxic dermatitis
 - Photodynamic therapy
 - Photoallergic dermatitis
 - Hydroa vacciniforme
 - Polymorphic light eruption
 - Actinic prurigo
 - Solar urticaria
- **Chronic photodermatoses**
 - Persistent light reaction
 - Photosensitive eczema
 - Actinic reticuloid
 - Brachioradial pruritus.

Before considering the various photodermatoses, brief mention is made of the complications of therapy using psoralens plus ultraviolet-A light (PUVA therapy). This therapy has been an effective treatment for psoriasis and some other dermatoses for many years. Several studies have shown an increased risk of skin cancers in these patients, particularly those who have received high doses.¹⁸³ For example, in one study of patients who had received cumulative UVA doses greater than 2000 J/cm², 19% had developed squamous cell carcinomas and 46% solar keratoses.¹⁸⁴ Interestingly, none of the 13% of patients without PUVA lentigines (see p. 841) had developed keratoses or squamous

cell carcinomas.¹⁸⁴ A Swedish study, published in 1999, found an increased incidence of squamous cell carcinoma in patients treated with PUVA but no increased risk of melanoma, despite concern that melanomas might be a consequence.¹⁸⁵ However, trioxsalen bath PUVA and newer low-dose regimens may reduce the risk of the development of skin cancer.^{186–188} Human papillomavirus was detected in some of the skin tumors that developed in one patient with PUVA-related lesions.¹⁸⁹

The effects of naturally occurring UVB have been studied in southern Chile at the edge of the Antarctic ozone hole. During periods of increased UVB radiation, sunburn was increased and photosensitivity disorders were slightly increased.¹⁹⁰ Alpine skiing is a recreation that leads to increased UV exposure.¹⁹¹ Car travel can also result in ultraviolet exposure (UVA) that may be enough to trigger a flare of polymorphic light eruption.¹⁹²

In a study of 203 patients presenting with 'photosensitivity', the most frequent diagnoses were polymorphic light eruption (26% of cases), chronic actinic dermatitis (17%), photoallergic contact dermatitis (8%), systemic phototoxicity to therapeutic agents (7%), and solar urticaria (4%).¹⁹³ Of the remainder, 22% proved not to have photosensitivity, no diagnosis could be made in 12% because of failure of follow-up, and 4% had allergic contact dermatitis.¹⁹³ Photodermatoses occur regularly in African Americans, the most common being polymorphic light eruption.^{194,195}

Photodamage has important consequences. Skin cancer and photoaging are the most important of these effects.¹⁹⁶ The skin naturally uses antioxidants to protect itself from photodamage. Antioxidants such as vitamin C, vitamin E, selenium, zinc, silymarin, soy isoflavones, and tea polyphenols may favorably supplement sunscreen protection and provide additional anticarcinogenic protection.¹⁹⁶ However, it seems that some individuals are not interested in the consequences of photodamage. It has been suggested that persons who chronically and repetitively expose themselves to ultraviolet light (UVL) to tan may have a novel type of UVL substance-related disorder.^{197,198} Nevertheless, photodermatoses have a significant impact on the quality of life of some patients, particularly those with actinic prurigo and photoaggravated dermatoses.¹⁹⁹

It is important to note that cases of '**pauci-inflammatory photodermatitis**' occur.²⁰⁰ Despite conspicuous clinical lesions, the histological changes are mild with telangiectasia and sparse perivascular lymphocytes.²⁰⁰

The account that follows is confined to the photodermatoses. Solar urticaria was discussed with the urticarial reactions (see p. 228). The following entities are discussed in turn:

- **Photosensitive genodermatoses**
 - Xeroderma pigmentosum
 - Cockayne's syndrome
 - Bloom's syndrome
 - Hartnup disease
 - Rothmund–Thomson syndrome
 - Smith–Lemli–Opitz syndrome
 - Kindler's syndrome
- **Phototoxic dermatitis**
- **Photodynamic therapy**
- **Photoallergic dermatitis**
- **Hydroa vacciniforme**
- **Polymorphic light eruption**
- **Actinic prurigo**
- **Chronic photodermatoses**
 - Persistent light reaction
 - Photosensitive eczema
 - Actinic reticuloid
 - Brachioradial pruritus.

PHOTOSENSITIVE GENODERMATOSES

The photosensitive genodermatoses are discussed here for completeness. Several of them have been discussed in other chapters. Most are exceedingly rare.

Xeroderma pigmentosum

Xeroderma pigmentosum is a rare, autosomal recessive genodermatosis characterized by deficient DNA repair and the early development of mucocutaneous cancers, particularly in sun-exposed areas (see Chapter 9, p. 315). A severe sunburn reaction usually occurs before the age of 2 years.

Cockayne's syndrome

Cockayne's syndrome is characterized by growth retardation, photosensitivity, deafness, mental deficiency, large ears and nose, and sunken eyes.²⁰¹ Two types have been identified: Cockayne's syndrome type 1 (OMIM 216400) due to a gene defect on chromosome 5q12 that encodes the group 8 excision-repair cross-complementing protein (ERCC8); and Cockayne's syndrome type 2 (OMIM 133540) due to a defect in the *ERCC6* gene on chromosome 10q11, involving cross-complementing group 6.

Bloom's syndrome

Bloom's syndrome (OMIM 210900), also known as congenital telangiectatic erythema, is a rare autosomal recessive disorder due to a defect in the *RECQL3* gene on chromosome 15q26.1. It is characterized by a telangiectatic, photosensitive facial eruption, stunted growth, proneness to respiratory and gastrointestinal infections, and predisposition to the early development of malignancies.²⁰² It is discussed with the poikilodermas (see Chapter 3, p. 77).

Hartnup disease

Hartnup disease (OMIM 234500) is due to mutations in the *SLC6A19* gene on chromosome 5p15. There is a photosensitive, pellagra-like skin rash in addition to cerebellar ataxia and mental disturbances. There may be some improvement in photosensitivity later in life (see Chapter 18, p. 571).

Rothmund–Thomson syndrome

Rothmund–Thomson syndrome (OMIM 268400), also known as poikiloderma congenitale, is due to mutations in the *RECQ4* helicase gene that maps to chromosome 8q24.3. The photosensitivity might be related to reduced DNA repair capacity (see Chapter 3, p. 76).

Smith–Lemli–Opitz syndrome

This syndrome (OMIM 270400) is an autosomal recessive disorder caused by mutations in the *DHCR7* gene on chromosome 11q12–q13 that result in a deficiency in the enzyme 7-dehydrocholesterol reductase (07-DHCR), which catalyzes the final step in cholesterol biosynthesis. It is characterized by learning disability associated with one or more of the following features: failure to thrive, dysmorphic facies, cataracts, congenital heart disease, hypospadias, second/third toe syndactyly, and severe photosensitivity.^{181,203} The sensitivity is to the UVA spectrum.¹⁸²

Kindler's syndrome

Kindler's syndrome (OMIM 173650) is a rare autosomal recessive genodermatosis characterized by trauma-induced blistering, poikilo-

derma, and varying degrees of photosensitivity.²⁰⁴ The gene responsible, *KIND1*, encodes a protein called kindlin-1, which is involved in linkages of other structures to the actin cytoskeleton. It leads to defects in keratinocyte adhesion and increased apoptosis. Photosensitivity has an early onset in some individuals.²⁰⁴ It has been included in the latest classification of epidermolysis bullosa, as a variant of this condition (see p. 76).

PHOTOTOXIC DERMATITIS

Phototoxicity is the damage induced by UV and/or visible radiation as a result of contact with or the ingestion of a photosensitizing substance.²⁰⁵ It does not depend on an allergic reaction and is therefore akin to an irritant contact dermatitis.²⁰⁶ **Phytophotodermatitis** is a photosensitivity reaction, usually phototoxic in type, that results from contact with plants containing psoralens and other furocoumarins.^{207–209} The families Umbelliferae and Rutaceae contain many phototoxic species.²¹⁰ They include celery,^{207,211,212} parsnips, carrots, fennel, dill, giant hogweed, zabon (*Citrus maxima*),²¹⁰ limes, and lemons.²¹³ Figs also produce phytophotodermatitis; they are of the family Moraceae. Herbal therapies applied to the skin can induce a phytocontact dermatitis.²¹⁴ Phytophotodermatitis in children is sometimes mistaken for child abuse.²¹⁵

Clinically, phototoxic reactions resemble an exaggerated sunburn reaction with dusky erythema; when severe, vesiculation may occur, followed by desquamation and hyperpigmentation.^{216–218} Two patterns of reaction are seen: an immediate reaction, which follows the ingestion of the photosensitizing agent and involves exposed areas such as the face, ears, V area of the neck, and dorsum of the hands;²¹⁹ and a delayed reaction, which follows contact with psoralens and peaks after 2 or 3 days. The reaction is limited to the site of contact with the photosensitizing agent. Prominent pigmentation lasting for weeks or months may follow phytophotodermatitis.²⁰⁷ In some instances, the preceding erythematous phase may go unnoticed.²⁰⁸ Chronic changes include wrinkling, atrophy, telangiectasia, and the formation of keratoses.

Another presumed phototoxic reaction is the formation of subepidermal bullae, first reported in patients with chronic renal failure receiving high doses of furosemide (frusemide).²²⁰ Other drugs that may produce this pseudoporphyria reaction (see p. 578) include naproxen,²²¹ oxaprozin, pravastatin, mefenamic acid, nabumetone, flutamide, dapsone, tetracycline, pyridoxine, nalidixic acid,²²² vinblastine,²²³ imatinib,²²⁴ and metformin.²²⁵ A list of drugs producing photosensitivity reactions has been published.²²⁶ Prolonged sunbed exposure of chronically sun-damaged skin has also been incriminated in producing pseudoporphyria, although whether there is any phototoxic component remains to be determined.²²⁷ Photo-onycholysis is another rare complication of certain drugs, including doxycycline,²²⁸ griseofulvin,²²⁹ indapamide, thiazides, captopril, and sparfloxacin.^{230,231}

Ingested drugs capable of causing a phototoxic reaction include, in addition to those mentioned previously, phenothiazines, thioxanthenes,²³² thiazides,^{233,234} doxycycline,²³⁵ fleroxacin,²³⁶ ofloxacin,²³⁷ sitafloxacin,²³⁸ enoxacin,²³⁸ sparfloxacin,²³⁸ tetrazepam,²³⁹ nonsteroidal anti-inflammatory drugs (NSAIDs),²⁴⁰ voriconazole,²⁴¹ retinoids,²⁴⁰ amiodarone,²⁴² atorvastatin,²⁴³ carbamazepine, and sulfonamides.^{216,244} Azathioprine therapy appears to photosensitize skin to subsequent UVA radiation.²⁴⁵ Phototoxic dermatitis has also resulted from ingestion of *Chenopodium album*, a weed-like plant consumed as a leaf vegetable.^{246,247} Topical agents associated with phototoxicity include coal tar and derivatives, psoralens,²⁰⁸ and textile dyes,²⁴⁸ as well as some perfumes and sun barrier preparations.²⁴⁹ The causes of a phototoxic dermatitis are listed in **Table 21.1**. A bullous phototoxic reaction has followed the use of aromatherapy oil containing bergamot, which contains furocoumarins.²⁵⁰ Tobacco smoke is phototoxic.²⁵¹

Table 21.1 Causes of a phototoxic dermatitis

Phytophotodermatitis

Contact with various plants, including vegetables and topical herbal therapies

Pseudoporphyria pattern

Acitretin	Imatinib
Amiodarone	Isotretinoin
Ampicillin–sulbactam	Ketoprofen
Aspirin	Mefenamic acid
β-Lactams	Metformin
Bumetanide	Nabumetone
Cefepime (?)	Nalidixic acid
Celecoxib	Naproxen
Chlorthalidone	Oxaprozin
Ciprofloxacin	Pravastatin
Cola consumption	Pyridoxine
Contraceptive pill	Rofecoxib
Cyclosporine (ciclosporin)	Sulfonamides
Dapsone	Tanning beds
Etretinate	Tetracyclines
Finasteride	Torsemide
5-Fluorouracil	UVB phototherapy
Flutamide	Vinblastine
Furosemide	Voriconazole
Hemodialysis	

Photo-onycholysis

Captopril	Indapamide
Doxycycline	Sparfloxacin
Griseofulvin	Thiazides

Other drugs

Amiodarone	Retinoids
Atorvastatin	Sitafloxacin
Carbamazepine	Sparfloxacin
Doxycycline	Sulfonamides
Enoxacin	Tetrazepam
Fleroxacin	Thiazides
NSAIDs	Thioxanthenes
Ofloxacin	Voriconazole
Phenothiazides	

Topical agents

Aromatherapy (bergamot)	Psoralens
Coal tar and derivatives	Sun barrier preparations
Perfumes	Textile dyes

Note: A full list of drugs is included in Litt JZ. *Drug Eruption Reference Manual*, 14th edn. London: Informa Healthcare, 2008.

A phototoxic reaction requires the absorption of photons of specific wavelengths by the photosensitizing substance.²⁴⁴ Energy is dissipated as it returns from an excited state to its ground state. Free radicals, peroxides, and other substances are formed that may potentially damage cellular and subcellular membranes.^{244,252} The action spectrum is usually in the UVA range, although with some ingested substances

Figure 21.7 (A) Severe phototoxic reaction with epidermal necrosis. (B) In this less severe phototoxic reaction that followed contact with a psoralen-containing plant (phytophotodermatitis), there are scattered ‘sunburn cells’ in the epidermis. (H&E)

(e.g., thiazides) it is in the shorter UVB wavelengths.^{216,233} The formation of apoptotic keratinocytes (‘sunburn’ cells) appears to require UVB radiation; tumor necrosis factor-α (TNF-α), p53 protein, and other factors are involved in some way.^{253–255} There is evidence that a p53-independent pathway can also be involved.²⁵⁶ Melanocytes, in contrast, are much more resistant to UV-induced apoptosis, due to a high level of antiapoptotic proteins such as Bcl-2. This protein is upregulated by nerve growth factor produced by keratinocytes exposed to UV irradiation.²⁵⁷ It is interesting to speculate whether this is the mechanism of the melanocytic hyperplasia seen in chronic sun-damaged skin.

Phototoxicity is more common than photoallergy, from which it differs by being dose related and by its subsidence on removal of the photosensitizer or the UV radiation. Some drugs produce both toxic and allergic reactions; in others, the mechanism has not been elucidated.

Histopathology

If the photosensitizing agent is applied to the skin, there is some ballooning of keratinocytes in the upper dermis, with epidermal necrosis in severe reactions²⁰⁶ and scattered apoptotic keratinocytes (‘sunburn cells’) in mild reactions (Fig. 21.7). There is variable spongiosis. A

Figure 21.8 Chronic photosensitivity. There are deeply extending basophilic elastotic fibers but no inflammation. (H&E)

similar picture is seen in biopsies taken from photopatch test sites in phototoxic states.²⁵⁸ If the chromophore reaches the skin through the vasculature, there may be only minor epidermal changes.²⁵⁹

In both instances, there is a mild or moderate superficial inflammatory cell infiltrate in the dermis.²⁵⁹ It is composed predominantly of lymphocytes, although a few neutrophils may be present in severe reactions. Eosinophils are sometimes seen. Although it is usually taught that the dermal infiltrate is both superficial and deep in the light-related dermatoses, this is not always so, particularly in acute lesions. Pigment incontinence is sometimes present,²³³ whereas in late lesions of phytophotodermatitis there is also basal hyperpigmentation.

In bullous phototoxic reactions (pseudoporphyria), there is a subepidermal blister with only rare inflammatory cells in the base (see p. 578). A very occasional eosinophil is sometimes present. In cases of long standing, the blisters may heal with scarring and milia formation.²⁵⁹ In chronic phototoxic states (bullous and nonbullous), basophilic elastotic fibers extend below the mid dermis (**Fig. 21.8**). There is also PAS-positive, diastase-resistant material in and around small blood vessels in the upper dermis. Fibroblasts and dendrocytes are also increased in photosensitivity reactions of some duration.

Small amounts of IgG and sometimes C3 are found adjacent to vessels and near the basement membrane zone in chronic states.²⁵⁹

Electron microscopy

In chronic phototoxicity, there is reduplication of the basal lamina in dermal vessels and fine fibrillar deposits in their vicinity.²⁵⁹

PHOTODYNAMIC THERAPY

Photodynamic therapy is used, selectively, in the treatment of some cutaneous malignancies. It involves the use of a photosensitizing agent that is applied to, or accumulates in, malignant tissue, followed by the application of a light source that activates the photosensitizer.²⁶⁰ This results in the release of toxic oxygen radicals that destroy the malignant cells. Side effects reported with photodynamic therapy include erythema, pain, burning, edema, itching, scaling, and pustule formation.²⁶¹ Partial-thickness burns have been reported following the ingestion of temoporfin, a second-generation photosensitizer.²⁶² Acute phototoxicity with urticarial features has also been reported from photodynamic therapy using topical 5-aminolevulinic acid.²⁶³

PHOTOALLERGIC DERMATITIS

Photoallergy is increased reactivity of the skin to UV and visible radiation and is brought about by a chemical agent on an immunological basis.^{205,259} The photosensitizing chemical is usually applied topically to the skin; uncommonly, photoallergic reactions may follow ingestion of a drug.^{205,264}

The usual photoallergic reaction develops 24–48 hours after sun exposure and is a pruritic, eczematous eruption.²⁶⁵ Lichenification may occur in cases of long standing. Lichenoid papules have been reported in some thiazide-induced photoallergic reactions.²⁶⁵ Photoallergic dermatitis occurs essentially on light-exposed areas, although there is a tendency for lesions to extend beyond the exposed areas. Regression usually occurs after 10–14 days, although in some cases the condition may persist for long periods and the patients become persistent light reactors (see later).

Topical agents that have been implicated in photoallergic reactions include fragrances such as musk ambrette²⁶⁶ and coumarin derivatives²⁶⁷ and also sunscreens containing benzophenones,^{268–272} oxybenzone, butyl methoxy dibenzoylmethane,²⁷² methoxycinnamate,²⁷³ or *para*-aminobenzoic acid and its esters.^{217,249,274} Benzophenones contained in products other than sunscreens can also produce photoallergic reactions.²⁷⁵ Benzocaine,²⁷⁶ isothipendyl chlorhydrate,²⁷⁷ piroxicam gel,²⁷⁸ ketoprofen,²⁷⁹ the canine NSAID agent carprofen through occupational exposure,²⁸⁰ fentichlor,²⁸¹ plants in the Compositae family, and, rarely, psoralens have been recorded as producing photoallergic reactions. A recent study described patients with photoallergic contact dermatitis to 8-methoxypsoralen in the sap of the common fig, *Ficus carica*. Photoallergy was demonstrated through patch testing with serial dilutions of this plant material.²⁸² The halogenated salicylanilides, which resulted in numerous cases of photoallergic dermatitis more than two decades ago, have been withdrawn as topical antibacterial agents.²⁸³ Photoallergic contact dermatitis involving particularly the lips and chin has resulted from using gargles and gels containing the NSAID agent benzydamine.²⁸¹ A recently reported retrospective chart review indicated that sunscreens and antimicrobial agents are the most frequent allergens producing photoallergic contact dermatitis; there has been a decline in those cases caused by fragrances and an increase in reactions to medications.²⁸⁴

Systemically administered drugs that rarely produce photoallergy include quinine,^{285,286} quinidine,^{287,288} griseofulvin, possibly itraconazole,^{289,290} terbinafine,²⁹¹ ranitidine,^{292,293} lomefloxacin,²⁹⁴ chlorpromazine,²⁹⁵ piroxicam,^{296–298} ampiroxicam,²⁹⁹ droxicam,³⁰⁰ piktetoprofen,³⁰¹ ketoprofen,^{302,303} voriconazole,^{241,304} esomeprazole,³⁰⁵ pyridoxine hydrochloride (vitamin B₆),^{306,307} tegafur,³⁰⁸ flutamide,^{309,310} alprazolam,³¹¹ sertraline (Zoloft®),³¹² triflusal,³¹³ nifedipine,³¹⁴ amlodipine,^{314,315} thiazides,³¹⁶ sulfonamides,³¹⁶ capecitabine,³¹⁷ celecoxib,³¹⁸ tenofovir,³¹⁹ the antipsychotic agent cyamemazine,³²⁰ certain tetracycline derivatives, diphenhydramine,³²¹ tolbutamide, ibuprofen,³²² herbal treatments,³²³ fibric acid derivatives (e.g., fenofibrate and clofibrate),^{324–326} chlor-diazepoxide, and cyclamates.^{249,259} The author's experience of the more common drugs producing photosensitive reactions during the past 10 years is shown in **Table 21.2**. These observations are based on the consequences of drug cessation but not subsequent rechallenge. Drugs that may produce a lichenoid photoallergic reaction include, in addition to thiazide diuretics (discussed previously), demeclocycline, enalapril, quinine, quinidine, and chloroquine.²⁴⁰ A flagellate dermatitis, resembling that produced by bleomycin (see p. 452), has been reported after the ingestion of raw shiitake mushrooms.^{327,328} A photo-distributed pustular drug eruption, with overlap features between Sweet's syndrome and acute generalized exanthematous pustulosis, has been associated with antidepressant therapy.³²⁹ The various drugs producing photoallergic reactions are listed in **Table 21.3**.

Table 21.2 The author’s experience of the common causes of photodrug reactions

NSAIDs	Ibuprofen Furosemide
Diuretics	Hydrochlorothiazide Hydrochlorothiazide combined with ACE inhibitor
Ca ²⁺ channel blockers	Amlodipine Nifedipine Diltiazem
Antiarrhythmic	Amiodarone
Antibiotic-associated photodrug reactions to doxycycline and the quinolones are well known and rarely biopsied.	

Table 21.3 Causes of a photoallergic dermatitis

Topical agents	
Benzocaine	Fragrances
Benzophenones in other products	Ketoprofen
Compositae	Piroxicam gel
Coumarin derivatives	Sunscreens
Systemically administered drugs	
Alprazolam	Ketoprofen
Amlodipine	Lomefloxacin
Ampiroxicam	Nifedipine
Azathioprine	Piketoprofen
Capecitabine	Piroxicam
Celecoxib	Pyridoxine hydrochloride (vitamin B ₆)
Chlordiazepoxide	Quinapril
Chloroquine	Quinidine
Chlorpromazine	Quinine
Cyclamates	Ranitidine
Demeclocycline	Rofecoxib
Diphenhydramine	Sertraline (Zoloft®)
Droxicam	Sulfonamides
Enalapril	Tegafur
Fibric acid derivatives (e.g., fenofibrate and clofibrate)	Tetracycline derivatives
Flutamide	Thiazides
Griseofulvin	Tolbutamide
Herbal treatments	Triflusal
Ibuprofen	Voriconazole
Itraconazole	
Lichenoid photoallergic reaction	
Chloroquine	Quinidine
Demeclocycline	Quinine
Enalapril	Thiazides
Flagellate dermatitis	
Shiitake mushrooms	
Photo-pustular eruption	
Antidepressant therapy	

Three factors are required in a photoallergic reaction: a photosensitizing agent, light (usually in the UVA range), and a delayed hypersensitivity response.²⁰⁵ The absorption of light energy appears to alter the photosensitizing chemical in some way to produce a hapten that attaches to a protein carrier and eventually stimulates immunocompetent cells, producing a hypersensitivity response.²⁴⁴ Photopatch testing is used to elucidate the offending agent.³³⁰ The standard set of photoallergens has to be updated periodically to accommodate changing formulary of topical preparations.³³¹

Histopathology^{206,244}

The changes resemble those seen in contact allergic dermatitis and include epidermal spongiosis, spotty parakeratosis, and some acanthosis.^{219,285} Spongiotic vesiculation occurs in severe cases. There is a moderately heavy infiltrate of lymphocytes, mainly in a perivascular location in the upper dermis. A few eosinophils are usually present. There is some exocytosis of these inflammatory cells. In some instances, the dermal reaction differs from that seen in contact allergic dermatitis by deeper extension of the infiltrate. This is particularly so in lesions of long standing. Stellate cells and telangiectasia may be prominent, reflecting the photosensitive component. Conspicuous solar elastotic changes may also develop in chronic cases.

The lichenoid papules show a lichenoid tissue reaction with a superficial and mid-dermal inflammatory cell infiltrate. Spongiosis is sometimes present as well.²⁴⁰ Changes of photosensitivity (telangiectasia, stellate cells, deep extension of the infiltrate, and increased solar elastosis) are usually present, but they take 3 or 4 weeks or more to develop.

HYDROA VACCINIFORME

Hydroa vacciniforme is a rare, debilitating photodermatosis of unknown pathogenesis.³³² It is manifested clinically by the development of erythema and vesicles, on uncovered skin, within 1 or 2 days of sun exposure.^{332,333} The vesicles heal leaving varioliform scars. Ear mutilation has been reported as a consequence of recurrent lesions with scarring.^{334,335} Oral lesions have been reported.^{336,337} Rarely, there are crusted, nonvesicular lesions.³³⁸ The disease usually begins in childhood and runs a chronic course before remitting in adolescence.³³⁹ Late onset³⁴⁰ and familial cases are exceedingly rare.^{341,342} Coexistence with a malignant lymphoma has been documented.³⁴³ Porphyrins are normal. Lesions may be reproduced in many instances by repeated exposures to UVA radiation.^{344–348} Dietary fish oil, which provides some systemic photoprotection, has produced variable clinical responses in this disease.³⁴⁹

Approximately 20 years ago, attention was drawn to a hydroa vacciniforme-like eruption associated with latent Epstein–Barr virus (EBV) infection, which had a high propensity to develop cutaneous lymphoma, usually of subcutaneous type.^{350–353} Latent EBV infection has now been detected in the dermal infiltrate of children with typical manifestations of hydroa vacciniforme.^{350,354} Often, cases associated with EBV have lesions on both sun-exposed and protected areas of the body, but there are several reports of EBV-associated hydroa vacciniforme limited to the face.³⁵⁵ Severe cases are often associated with natural killer (NK) cell lymphocytosis, hypersensitivity to mosquito bites, and fatal hemophagocytic syndrome. Progression to NK/T-cell lymphoma is another cause of death in these severe cases.³⁵⁶ In some cases, the lymphoma associated with hydroa vacciniforme-like lesions can have a prolonged clinical course.³⁵⁷ It has been suggested that both the typical and the atypical forms are part of a spectrum, in which the atypical lesions have the potential to lead to an EBV-associated lymphoid malignancy.^{350,358} Lesions of hydroa vacciniforme can be induced in patients with latent EBV infection by repeated UVA irradiation.³⁵⁹

Figure 21.9 Hydroa vacciniforme. (A) There is reticular degeneration, with intraepidermal vesiculation and necrosis. The underlying dermis shows a mixed inflammatory cell infiltrate, predominantly lymphocytes in this example. (B) High-power view showing detail of the intraepidermal vesiculation. The vesicles are filled with serum and fibrin and contain scattered inflammatory cells. (H&E)

The exact status of **hydroa estivale** is uncertain.^{360,361} It has been regarded in the past as a mild form of hydroa vacciniforme or a childhood form of polymorphic light eruption³⁴⁴ or actinic prurigo (see later). Some of the earlier reported cases may have been erythropoietic protoporphyria.^{362,363}

Histopathology

The established lesions of hydroa vacciniforme show intraepidermal vesiculation with reticular degeneration and, later, confluent epidermal necrosis.³⁴⁴ The vesicles are filled with serum, fibrin, and inflammatory cells (Fig. 21.9). Ulcerated lesions may be associated with superficial dermal necrosis.³⁶² Vascular thrombosis is sometimes present in these circumstances. Lymphocytes and neutrophils are present at the lower border of any necrotic zone. In addition, there is a superficial and deep

perivascular infiltrate of lymphocytes and occasionally a few eosinophils. There are no PAS-positive deposits.³⁶² A dense peri-eccrine infiltrate of small and medium-sized lymphocytes may be present.³⁶⁴ In some severe cases, a lobular or septal panniculitis may also be present. Healed lesions show variable scarring in the upper dermis.³³⁸

In lymphoma-associated cases, dense dermal infiltrates involve the dermis and extend into the subcutis. Geographic necrosis and reactive germinal centers have been described in some cases,³⁶⁵ and angiocentricity or angioinvasion may be prominent.³⁶⁶ Immunohistochemical findings have varied somewhat significantly from study to study. The lymphoid cells are often CD45RO positive with varying numbers of CD56⁺ cells; CD20 staining is generally negative.³⁶⁷ Cytotoxic granule proteins, such as TIA-1, perforin, and granzyme B, are often found.^{365,367} On the other hand, other examples with a more indolent clinical course are negative for CD56.³⁵⁷ Another recent study reported that the majority of hydroa vacciniforme lesions do not show significant numbers of CD56⁺ cells beyond expected background staining – a result that stands in contrast to **hypersensitivity to mosquito bites**, another EBV-associated disorder in which lesions contain many CD56⁺ cells. Peripheral blood lymphocytes of hydroa vacciniforme patients contain EBV⁺ γ/δ T cells, whereas those of patients with hypersensitivity to mosquito bites are composed of EBV⁺ NK cells.³⁶⁸ Overlap of these two disorders also exists.^{368,369} In still another study of 12 patients, 8 of whom died of their disease, the infiltrates had a cytotoxic (CD8⁺) profile and were negative for CD4, CD30, and CD56.³⁶⁶ The conclusion drawn from all of this information, to date, is that there is a strong association between hydroa vacciniforme lesions, EBV infection, and lymphoma, but with phenotypic variability and a disease course that ranges from indolent to rapidly progressive.

Direct immunofluorescence sometimes shows scattered granular deposits of C3 at the dermoepidermal junction.³⁴⁴ EBV-encoded RNA (EBER) can be identified in dermal lymphocytes.³⁶⁴ It was found in 28 of 29 patients in a study of patients with hydroa vacciniforme or severe hydroa vacciniforme-like eruptions.³⁵⁶

POLYMORPHIC LIGHT ERUPTION

Polymorphic light eruption (polymorphous light eruption) is an idiopathic photodermatosis in which lesions of varied morphology appear several hours or even days after exposure to the sun and subside in a further 7–10 days if further exposure is avoided.^{370–373} Certain populations appear to be genetically predisposed: in Finland, cases with an autosomal dominant mode of inheritance, with reduced gene penetrance, have been reported.³⁷⁴ Twin studies and genetic modeling have also established a clear genetic influence.^{375–377} Polymorphic light eruption affects 10–20% of those living in temperate climates;^{372,378,379} it is much less common in populations living nearer to the equator.³⁸⁰ The prevalence in the Northern Hemisphere is approximately 15%. It is very uncommon in subtropical Brisbane, Australia (author's personal experience), yet it is not uncommon 1000 miles to the south.³⁸¹

The lesions may take the form of small pruritic papules, papulovesicles, or urticarial plaques.³⁸² The papulovesicular form (pinpoint papular variant) has been regarded as a discrete subset.^{383–385} Rarely, lesions may resemble those seen in erythema multiforme or insect bites.³⁸² Eczematous lesions and lesions resembling those of prurigo nodularis³⁸⁶ have been described,^{387,388} although these variants are not universally accepted as part of the spectrum of polymorphic light eruption.³⁸² Lesions are usually monomorphous in the same individual.³⁸⁹ Spring and summer eruption of the elbows has been suggested to be a localized variant of polymorphic light eruption.³⁹⁰ The severity of the disease is highly variable.³⁹¹ Sun-related pruritus may rarely precede the onset of the disease.³⁹² Contact and photocontact allergies are present, rarely, in patients with polymorphic light eruption.³⁹³

Lesions have a predilection for the dorsum of the hands and forearms, the upper part of the arms, the neck, and the face.³⁹⁴ The face is usually spared in the papulovesicular form. The photodermatosis known as ‘juvenile spring eruption of the ears’, a condition found predominantly in young boys, is a probable variant of polymorphic light eruption.³⁹⁵ ‘Lambing ears’, a blistering and crusting disorder of the pinnae of farmers at lambing time, is a variant of juvenile spring eruption with unusual demographics.³⁹⁶ The mean age of onset of polymorphic light eruption is in the third decade of life.³⁹⁷ In most series, there has been a female preponderance.^{382,398}

Various associations have been reported, some of which may be fortuitous. They include common variable hypogammaglobulinemia,³⁹⁹ thyroid disease,⁴⁰⁰ and lupus erythematosus.^{401–403} A study of patients with elevated titers of antinuclear antibodies with polymorphic light eruption found no progression to lupus erythematosus in any of the patients after a median follow-up period of 8 years.⁴⁰⁴ Lesions have rarely been limited to areas of vitiligo⁴⁰⁵ or nevoid telangiectasia.⁴⁰⁶ Psychological distress has been reported in more than 40% of individuals with the disease.⁴⁰⁷

The condition is chronic in nature, although in approximately half the cases there is diminished sensitivity to sunlight over time, with periods of total remission; light sensitivity increases in some patients.^{397,408–410} The phenomenon of eventual tolerance to sunlight is known as ‘hardening’.⁴¹¹ Accordingly, prophylactic phototherapy using PUVA therapy is used in the treatment of the disease.⁴¹² Some studies suggest that a delayed hypersensitivity reaction to sunlight-modified skin antigens is involved in the pathogenesis.^{413–415} In other words, polymorphic light eruption is an autoimmune disease against a UV radiation-induced cutaneous antigen.⁴¹⁶ In normal subjects, UV exposure leads to a disappearance of Langerhans cells from healthy skin 48–72 hours later and an accumulation of CD11b⁺ (Mac1) macrophage-like cells, which reportedly produce interleukin-10 (IL-10). In patients with polymorphic light eruption, Langerhans cells do not disappear after UV exposure, and CD11b⁺ cells, already present at the time of exposure, further increase and invade the epidermis.⁴¹⁷ There is a reduced expression of TNF- α , IL-4, and IL-10 in the UVB-irradiated skin of patients with polymorphic light eruption that is largely attributable to a lack of neutrophils and is indicative of reduced Langerhans cell migration.⁴¹⁸ In other words, there is a defect of UV-induced immunosuppression in this disease.⁴¹⁹ There is also impairment of UV-induced, allergen-specific immune tolerance that may play a role in promoting recurrent polymorphic light eruption.⁴²⁰ There is normalization of UVB-induced trafficking of Langerhans cells and neutrophils after artificial UVB ‘hardening’.⁴²¹ The action spectrum appears to be quite broad and may involve both the UVA and the UVB range,^{422–425} although UVA radiation appears to be the more important.^{380,426,427} An eruption similar to the polymorphic light eruption has been reported in welders due to UVC light.⁴²⁸ There is no significant relationship between the ease of provocation of the disease by UVA and/or UVB radiation and clinical disease severity.⁴²⁹

The management of polymorphic light eruption primarily involves preventative measures such as avoidance of sun exposure and use of sunscreens with high UVA protection.⁴³⁰ The use of phototherapy in an attempt to produce ‘hardening’ was mentioned previously. Systemic immunosuppression may be required in severe cases.⁴³⁰

Histopathology^{372,382,394}

There is marked variability in the histopathological changes in the various clinical subsets of polymorphic light eruption (Figs. 21.10 and 21.11). However, a fairly constant feature (in keeping with the mnemonic mentioned on page 22) is the presence of a dermal inflammatory cell infiltrate that is both superficial and deep, although if early lesions are biopsied, it may not extend below the mid dermis. Although the infiltrate is predominantly perivascular, there is sometimes a heavy

Figure 21.10 Polymorphic light eruption. Note the superficial and deep perivascular infiltrate in the dermis. There is subepidermal edema and spongiotic vesiculation. (H&E)

interstitial infiltrate of lymphocytes in the upper dermis in those variants characterized by prominent subepidermal edema. The lymphocytic infiltrate is composed of T cells,^{431,432} and there is evidence that these cells are CD4⁺ in early lesions and predominantly CD8⁺ in later lesions.⁴³³ Various interleukins may act as lymphocyte attractants.⁴³⁴ Eosinophils are sometimes present in the dermal infiltrate, whereas in the papulovesicular type, a few neutrophils have sometimes been recorded. A rare neutrophil-rich variant occurs.⁴³⁵

Edema of the upper dermis is often present and is quite prominent in plaque-like lesions. In the rare erythema multiforme-like lesions, this may be so marked that subepidermal bullae form.³⁸² However, there is no lichenoid (interface) reaction as occurs in erythema multiforme. Extravasation of red cells is sometimes seen in the upper dermis, particularly in the papulovesicular form.⁴³⁶ Unlike lupus erythematosus, there are no dermal deposits of acid mucopolysaccharides.⁴³⁷

The epidermal changes are variable depending on the clinical type. The epidermis may be normal or show slight changes such as very mild spongiosis, focal parakeratosis, or acanthosis. In the papulovesicular form, there is invariably spongiosis leading to spongiotic vesiculation.⁴³⁶ There is often some basal vacuolation but no basement membrane thickening. Scattered apoptotic keratinocytes are often present in the papulovesicular variant. This may be accompanied by exocytosis of lymphocytes and erythrocytes.⁴³⁶ In the papulovesicular form, there may also be claw-like extension of epidermal rete ridges at the lateral boundaries of each papule, reminiscent of lichen nitidus.³⁸⁵

Direct immunofluorescence gives variable results. Focal perivascular and interstitial deposits of fibrin and perivascular C3 or IgM have all been recorded in a few cases.⁴³⁸ The lupus band test is negative.⁴³⁹

Differential diagnosis

The variable epidermal changes in polymorphic light eruption can resemble other inflammatory dermatoses, particularly forms of eczematous dermatitis. Papillary dermal edema has been touted as a characteristic feature of polymorphic light eruption (at least in plaque-type lesions), but as noted by Pincus *et al.*, this change can also be seen in lupus erythematosus (LE) – not only in acute cutaneous LE but also in acute and chronic discoid LE – and also in dermatomyositis.⁴⁴⁰ In addition, superficial and deep dermal lymphocytic infiltrates can mimic those of lupus erythematosus, lymphocytoma cutis, and

Figure 21.11 Polymorphic light eruption. (A) There is a superficial and deep perivascular infiltrate of lymphocytes. (B) In this case, there is massive subepidermal edema and (C) a tight deep perivascular infiltrate of lymphocytes. (H&E)

lymphocytic infiltration of Jessner (which may in reality represent tumid lupus erythematosus). Interface dermatitis (when present) argues more strongly for lupus erythematosus, whereas significant dermal mucin deposition, periadnexal infiltrates, and clusters of CD123⁺ plasmacytoid dendritic cells favor lupus erythematosus. Studies of lymphocyte subpopulations do not allow a clear separation among these dermatoses, with the exception of a significant B-cell component in lymphocytoma cutis. The rare neutrophil-rich variant of polymorphic light eruption bears a resemblance to Sweet's syndrome, which can sometimes be photo-aggravated. However, polymorphic light eruption is more likely to have an admixture of other cell types, including lymphocytes and eosinophils, and it differs from Sweet's syndrome by an absence of fever, underlying disease, or abnormalities in white blood cell count, erythrocyte sedimentation rate, or C-reactive protein.⁴⁴¹

ACTINIC PRURIGO

Actinic prurigo (Hutchinson's summer prurigo,⁴⁴² hereditary polymorphic light eruption)^{443,444} is a chronic photodermatitis occurring predominantly in North American Indians and in Central America, although people of European origin and Asians are not spared.^{445–451} Actinic prurigo has been regarded as a variant of polymorphic light eruption,⁴⁴⁵ although this has been challenged on the basis of its distinct HLA typing.⁴⁵² It is possible that the characteristic actinic prurigo phenotype is determined by this HLA type (DRB1*0407), found in 70% of patients.^{451,453} An association with DRB1*14 has been reported in an Inuit population.⁴⁵⁴ Both actinic prurigo and polymorphic light eruption may share a common pathophysiological basis.^{376,455,456} Families with members having either disease have been reported.^{376,457} Light testing gives inconsistent results, although the majority are sensitive to UVA light.

Actinic prurigo is characterized by onset in childhood; female preponderance; a familial tendency, which is quite high in some communities; and severe pruritus.^{445,446,458} It appears to be inherited as a dominant trait but with incomplete penetrance.⁴⁵⁹ It commences as an eczematous eruption on exposed areas, particularly the face, earlobes, and forearms.⁴⁴³ Covered areas are involved in some patients but not others.⁴⁶⁰ Papular, plaque-like and prurigo-like papulonodules develop.⁴⁴⁶ Lichenification and postinflammatory scarring can be marked.⁴⁵¹ Other features that may be present include an exudative and crusted cheilitis of the lower lip,⁴⁶¹ conjunctivitis,⁴⁶² and alopecia of the eyebrows.⁴⁴⁵ Primary cutaneous B-cell lymphoma has developed in two patients.⁴⁶³ A study of Asian patients with actinic prurigo showed that male adults are more commonly affected and there is an absence of mucosal involvement.⁴⁶⁴

One study found that in those who developed actinic prurigo as children and teenagers, it was more often associated with cheilitis, acute eruptions, and improvement over 5 years, whereas adults tended to have a milder and more persistent dermatosis.⁴⁶⁵

The pathogenesis may result from excessive TNF- α production by keratinocytes, triggered by UV light in genetically predisposed individuals.⁴⁶⁶ The dermal infiltrate is composed of T-helper type 1 (CD4⁺) lymphocytes admixed with scattered B cells and dermal dendrocytes.⁴⁶⁶

Treatment options include photoprotection, topical and oral corticosteroids, phototherapy, thalidomide, cyclosporine (cyclosporin), and antimalarials.^{451,467,468} Thalidomide appears to modify the immune response by inhibition of TNF- α synthesis.⁴⁶⁹

Histopathology⁴⁴⁵

The findings are not diagnostically specific. There is usually hyperkeratosis, irregular acanthosis, prominent telangiectasia of superficial

Figure 21.12 Actinic prurigo. There is a shallow ulcer with neutrophils and fibrin deposition. Other changes include adjacent acanthosis with spongiosis and telangiectasia of superficial dermal vessels. These findings are nonspecific, and therefore clinical history is important in establishing the correct diagnosis. (H&E)

vessels, and a moderately heavy chronic inflammatory cell infiltrate that is predominantly lymphocytic and perivascular.⁴⁷⁰ Lymphoid follicles may be present. The cellular infiltrate is usually confined to the superficial plexus, but extension around mid-dermal vessels may occur. Solar elastosis is not a consistent finding. In early eczematous lesions, there is some epidermal spongiosis. Excoriation and changes of lichen simplex chronicus are present in the prurigo-like areas (Fig. 21.12).⁴⁷¹

The cheilitis is characterized by a dense lymphocytic infiltrate, often with well-formed lymphoid follicles – follicular cheilitis.^{471,472} A similar follicular pattern is often present in the conjunctiva.⁴⁷³

In actinic prurigo patients, there is a significant increase in CD3, CD4, CD8, CD45RO, and CD45RB lymphocytes.⁴⁶⁷ Langerhans cells are also increased.

CHRONIC PHOTODERMATOSES (CHRONIC ACTINIC DERMATITIS)

The terms ‘chronic photodermatoses’ and ‘chronic actinic dermatitis’ refer to a group of rare photodermatoses with overlapping clinical features that include persistent photosensitivity, a marked predominance in older males, and the presence of erythematous, edematous, and lichenified plaques in areas exposed to light.^{474–480} These conditions appear to be more common in Europe than in other areas of the world,^{476,481–483} suggesting the possible etiological role of a photosensitizing agent. A report of the phototest results of 86 patients with this condition showed that 74% had a positive result: 36% of these positive patients were sensitive to sesquiterpene lactone mix (the main allergenic constituent of Compositae plants), 21% to fragrance compounds, 20% to colophony, and 14% to rubber chemicals.⁴⁷⁸ In a study performed in New York City, positive patch test reactions to *para*-phenylenediamine were found among chronic actinic dermatitis patients in greater than expected numbers.⁴⁸⁴ Compositae appear to play no role in the United States.⁴⁸⁵ In a series of 44 cases reported from Melbourne, Australia, 26 patients (78.8%) had at least one allergic, photoallergic, or combined allergic/photoallergic reaction.⁴⁷⁹

Included in the chronic photodermatoses are persistent light reaction, photosensitive eczema, and actinic reticuloid.⁴⁸⁶ The terms

‘chronic actinic dermatitis’⁴⁸⁷ and ‘photosensitivity dermatitis–actinic reticuloid syndrome’⁴⁸⁸ have also been used to embrace this group of photodermatoses, which differ from polymorphic light eruption in the age and sex of those involved and in the extreme photosensitivity. The term ‘chronic actinic dermatitis’ is being used increasingly for this group of chronic photodermatoses.^{485,488,489} Actinic reticuloid and brachioradial pruritus have unique clinical and histopathological features that distinguish them from the other chronic photodermatoses.⁴⁹⁰

There appears to be a weak association between chronic actinic dermatitis and infection with HIV; it may even be the presenting disorder.^{491–493} An association with the human T-lymphotrophic virus type 1 (HTLV-1) has also been reported.⁴⁹⁴

Abnormal phototest responses to UVA and/or UVB and/or increased sensitivity to visible light characterize this group of conditions.^{479,489} Accordingly, photoprotection is an important component in the management of these patients. Other treatments that have been used include phototherapy, topical corticosteroids, azathioprine, mycophenolate mofetil, and topical tacrolimus.^{495,496}

Persistent light reaction

The condition of persistent light reaction was first recognized in relation to the use of halogenated salicylanilides, when it was noticed that a photosensitive eczematous eruption continued after the withdrawal of the offending photosensitizer. The lesions may be confined to the area of application of the agent or be more generalized. Other features include a positive photopatch test to the agent and a sensitivity to UVB radiation and sometimes other wavelengths as well.⁴⁹⁷

Other agents have now been incriminated; these may be used topically or systemically. Musk ambrette, which is used not only in after-shave lotions and various cosmetics but also in certain foodstuffs, is often involved.^{497–499} Thiazide diuretics may also produce a photodermatosis that persists for many years after their withdrawal,⁵⁰⁰ as may chlorpromazine, promethazine, pyrimethione zinc, quinine, quinoxaline dioxide, furosemide (frusemide), and epoxy resins.⁴⁸⁶ Contact with hexachlorophene rarely produces a persistent light reaction.⁵⁰¹

Although the pathogenetic mechanisms are unknown, autosensitization of skin proteins with endogenous photosensitizers and a cellular hypersensitivity reaction to light have been suggested in preference to persistence of the initial photosensitizing agent.⁴⁸⁶

Histopathology⁴⁹⁷

There is epidermal spongiosis with focal parakeratosis and some acanthosis. Spongiotic vesiculation is present in florid cases. A moderately dense perivascular inflammatory cell infiltrate involves the upper and mid dermis. Superficially, the infiltrate may be more diffuse, and there may be exocytosis of inflammatory cells, particularly in the thiazide-related cases.⁵⁰⁰ The infiltrate is predominantly lymphocytic with occasional eosinophils, plasma cells, and mast cells. In cases of long standing, basophilic fibers, resembling those seen in solar elastosis except for their lack of coiling, extend into the lower dermis.

A similar dermal infiltrate can be produced in clinically uninvolved skin by the application of UVB radiation.⁴⁹⁷

Photosensitive eczema

Photosensitive eczema probably represents a photocontact allergic dermatitis in which the photoallergen is unrecognized, leading to persistence of the eczematous eruption.^{474,502} The skin shows increased sensitivity to UVB radiation. This entity should be distinguished from those eczematous processes that may be exacerbated by light, such as seborrheic dermatitis and some cases of atopic dermatitis. It appears that chronic actinic dermatitis is increased in patients with atopic dermatitis.^{503,504}

Figure 21.13 Chronic actinic dermatitis (photosensitive eczema). Findings include spongiosis, acanthosis, and a superficial perivascular infiltrate composed mainly of lymphocytes. A few apoptotic keratinocytes can be identified, and there is limited exocytosis of inflammatory cells. The findings are similar to those in photoallergic dermatitis. (H&E)

Histopathology

The picture resembles photocontact allergic dermatitis with epidermal spongiosis and a superficial perivascular inflammatory cell infiltrate (Fig. 21.13). The infiltrate extends deeper in the dermis than is usual in contact allergic dermatitis.

Actinic reticuloid

Actinic reticuloid has been separated from the other chronic photodermatoses on the basis of its histopathological picture, which shows a variable resemblance to a T-cell lymphoma.^{490,505,506} Actinic reticuloid has clinical features that overlap with those of photosensitive eczema and persistent light reaction.⁵⁰⁷ Differences include episodes of an erythroderma-like picture involving also non-exposed areas of the body and extreme sensitivity to UVB and UVA radiation and often to visible light as well.⁵⁰⁸⁻⁵¹⁰ A positive photopatch test is present in less than 10% of affected individuals, although contact allergic sensitivity without the involvement of radiation is sometimes present.⁴⁷⁶ Offending agents in this category include oleoresins of various plants in the Compositae family and certain fragrances.^{481,511,512} Persistent light reaction sometimes evolves into actinic reticuloid,^{513,514} indicating that the chronic photodermatoses (chronic actinic dermatitis) are part of a spectrum. Avoidance of UV/visible light often leads to sustained improvement.⁵¹⁵

The few reports of lymphoma developing in patients with actinic reticuloid appear to represent a chance occurrence, particularly because the patients with actinic reticuloid are usually elderly.^{516,517} Furthermore, DNA aneuploidy has not been demonstrated using DNA flow cytometry.⁵¹⁸ Clonal T cells have generally not been identified,⁵¹⁹ although in a recent case clinically resembling Sézary syndrome, T-cell clonality studies on peripheral blood showed a T-cell receptor β -chain gene rearrangement.⁵²⁰

Although the pathogenesis of actinic reticuloid is unknown, theories similar to those advanced for persistent light reaction have been proposed. Of interest is the finding that cultured fibroblasts from the skin of individuals with actinic reticuloid show cytopathic changes and inhibition of RNA synthesis after exposure to UVA radiation.^{521,522}

Figure 21.14 Actinic reticuloid. There is variable acanthosis. The inflammatory infiltrate is heaviest in the upper dermis. (H&E)

Histopathology^{482,490,523}

There is usually a dense, polymorphous infiltrate in the upper dermis that may be band-like or more diffuse with extension into the mid and lower dermis (Fig. 21.14). The infiltrate is composed of lymphocytes; a variable number of large lymphoid cells with hyperchromatic, convoluted nuclei; scattered stellate fibroblasts; and a few plasma cells and sometimes eosinophils. Immunoperoxidase studies have shown that the infiltrate is composed of polyclonal T lymphocytes, Langerhans cells, and HLA-DR-positive macrophages.^{519,524-527} There is often exocytosis of lymphocytes and of the atypical mononuclear cells into the epidermis, where they form small collections resembling the Pautrier microabscesses of mycosis fungoides. Although the dermal infiltrate contains a mixture of CD4⁺ and CD8⁺ lymphocytes, the epidermis contains a predominance of CD8⁺ cells, in contrast to cutaneous T-cell lymphoma.⁵²⁸ There may be mild spongiosis, but this is not nearly as prominent as in the other chronic photosensitivity disorders.⁵²³ A similar dermal infiltrate can be produced by irradiating uninvolved skin at certain wavelengths.⁵²⁹

The epidermis is usually acanthotic, and sometimes there is psoriasiform epidermal hyperplasia associated with thickened collagen in the papillary dermis, representing superimposed changes of lichen simplex chronicus (Fig. 21.15).^{523,530} Blood vessels may be increased in the papillary dermis, and these are lined by plump endothelial cells.

Under lower power magnification, the impression is often of a chronic eczematous dermatitis, but with minimal spongiosis and an excessive number of dermal cells for such a process. The finding of scattered hyperchromatic cells and stellate fibroblasts completes the picture.

Electron microscopy

The presence of Langerhans cells in the dermal infiltrate has been confirmed.⁵³¹ The atypical cells resemble the Sézary cell in having a hyperconvoluted nucleus.⁵³²

Brachioradial pruritus

Brachioradial pruritus is a rare and recurrent solar dermatopathy that presents as a localized pruritic dermatosis involving the brachioradial region of the arm. In some patients, cervical spine disease has been incriminated. Because there is usually a marginal increase in mast cells,

Figure 21.15 Actinic reticuloid. Note the 'vertically streaked' collagen in the papillary dermis, the stellate fibroblasts, and occasional hyperchromatic lymphocyte. (H&E)

many of which are enlarged, it is considered further with other mast cell disorders (see p. 1147).

Cutaneous infections
and infestations –
histological patterns

22

In this age of international travel, it is necessary for dermatopathologists to be familiar with the appearances of all cutaneous infections, including those that are sometimes dismissed euphemistically as ‘infections of other countries’. Unfortunately, there is a bewildering number of such infections, making it difficult to commit to memory the details of all of them. Further problems result from the variable morphological appearances that a particular infectious agent may produce. Factors that may influence the histopathological features of a cutaneous infection include the numbers and virulence of the organism, the host’s immunological response, the stage of evolution of the disease, prior treatment, and the presence of secondary changes resulting from rubbing and scratching or superimposed further infection. Because

certain infections may produce different histopathological changes under these various circumstances, it seems prudent to categorize the infections and infestations on an etiological rather than a morphological basis in the succeeding chapters. This traditional approach reduces unnecessary duplication.

Table 22.1 provides an outline of the morphological approach to infections of the skin and lists the various diseases that should be considered when a particular morphological feature is encountered in a biopsy. It does not include some of the very rare presentations of certain infections. These various infections and infestations are the subject of Chapters 23–30.

Table 22.1 Histological patterns in infections and infestations	
Morphological feature	Diseases to be considered
Palisading granulomas	Phaeohyphomycosis (p. 704); mycobacteriosis (p. 650); treponematosi s (p. 674); sporotrichosis (p. 705); cryptococcosis (p. 693); coccidioidomycosis (p. 699); cat-scratch disease (p. 668); lymphogranuloma venereum (p. 670); schistosomiasis (p. 762)
Tuberculoid granulomas	Tuberculosis (p. 650); tuberculids (p. 653); tuberculoid leprosy (p. 659); syphilis [late secondary or tertiary] (p. 674); dermatophytosis [Majocchi’s granuloma] (p. 686); cryptococcosis (p. 693); alternariosis (p. 706); histoplasmosis (p. 701); keloidal blastomycosis (p. 713); protothecosis (p. 715); leishmaniasis (p. 750); acanthamebiasis (p. 748); echinoderm injury (p. 759); <i>Vibrio</i> and <i>Rhodococcus</i> infection (p. 657)
Suppurative granulomas	Atypical mycobacterial infections (p. 654); lymphogranuloma venereum (p. 670); blastomycosis-like pyoderma* (p. 646); actinomycosis* (p. 709); nocardiosis* (p. 708); mycetoma* (p. 707); cryptococcosis (p. 693); aspergillosis (p. 712) and other deep fungal infections† (p. 705); protothecosis (p. 715)
Histiocyte granulomas	Infections by atypical mycobacteria (p. 654); lepromatous leprosy (p. 660); leishmaniasis (p. 750); malakoplakia [Michaelis–Gutmann bodies in cytoplasm] (p. 669)
Histiocytes and plasma cells	Rhinoscleroma (p. 666); syphilis (p. 675); yaws (p. 678); granuloma inguinale [often abscesses also] (p. 664)
Plasma cells prominent	Syphilis (p. 675); yaws (p. 678); lymphogranuloma venereum (p. 670); chancroid (p. 665); visceral leishmaniasis (p. 752); trypanosomiasis (p. 749); arthropod bites [an uncommon pattern]; <i>Vibrio</i> infection (p. 644)
Eosinophils prominent	Arthropod bites (p. 778); helminth infestation (p. 762); cnidarian (coelenterate) contact (p. 758); subcutaneous phycomycosis (p. 711)
Neutrophils prominent	Impetigo [subcorneal neutrophils] (p. 638); ecthyma (p. 641); cellulitis (p. 643); erysipelas [prominent superficial edema also] (p. 643); granuloma inguinale [microabscesses] (p. 664); chancroid [superficial neutrophils] (p. 665); disseminated tuberculosis in AIDS patients (p. 653); erythema nodosum leprosum (p. 662); Lucio’s phenomenon (p. 662); anthrax (p. 663); yaws (p. 678) and pinta (p. 678) [both have intraepidermal abscesses]; blastomycosis-like pyoderma (p. 646); actinomycosis (p. 709); nocardiosis (p. 708); mycetoma (p. 707); fungal kerion (p. 686); phaeohyphomycosis (p. 704); aspergillosis (p. 712); mucormycosis [also infarction present] (p. 710); flea bites (p. 778)
Parasitized macrophages	Rhinoscleroma (p. 666); granuloma inguinale (p. 664); lepromatous leprosy (p. 660); histoplasmosis (p. 701); leishmaniasis (p. 750); toxoplasmosis [pseudocysts present] (p. 754); <i>Penicillium</i> infection (p. 712)
Parasitized multinucleate giant cells or foreign body reaction	Various fungal infections; protothecosis (p. 715); schistosomiasis (p. 762); <i>Demodex</i> mites within tissues; some other mite infestations
Superficial and deep dermal perivascular lymphocytic inflammation	Leprosy [indeterminate stage] (p. 660); secondary syphilis [often plasma cells present] (p. 674); arthropod bites (p. 778) and coral reactions (p. 758) [usually interstitial eosinophils also]; onchocercal dermatitis [microfilariae in lymphatics] (p. 764)
Psoriasiform epidermal hyperplasia	Chronic candidosis (p. 691); tinea imbricata (p. 686); chronic dermatophytoses [rare] (p. 687)
Pseudoepitheliomatous or irregular epidermal hyperplasia	Amebiasis (p. 748); toxoplasmosis [rare] (p. 754); mucocutaneous leishmaniasis (p. 751); schistosomiasis (p. 762); chronic arthropod bite reactions [rare] (p. 778); yaws (p. 678); rhinoscleroma (p. 666); granuloma inguinale (p. 664); blastomycosis-like pyoderma [oblique follicles and draining sinuses] (p. 646); tuberculosis [tuberculosis verrucosa and some infections by atypical mycobacteria] (p. 650); <i>Vibrio</i> infection (p. 643); certain deep fungal infections†; human papillomavirus infections (p. 732); milker’s nodule (p. 721) and orf (p. 722) [both of these may have thin, long rete pegs]; verrucous herpes/varicella lesions in HIV infection (p. 727)
Folliculitis and/or perifolliculitis	Syphilis [rare cases] (p. 675); dermatophytoses (p. 684); pityrosporum folliculitis (p. 697); pyogenic bacterial infections (p. 638); herpes simplex (p. 724); herpes zoster (p. 728); <i>Demodex</i> infestations (p. 769); larva migrans [eosinophilic folliculitis] (p. 765)
Vasculitis	Erythema nodosum leprosum (p. 662); Lucio’s phenomenon (p. 662); ecthyma gangrenosum (p. 641); necrotizing fasciitis (p. 644); meningococcal and gonococcal septicemia (p. 648); recurrent herpes [‘lichenoid lymphocytic vasculitis’] (p. 724); cytomegalovirus infection [endothelial cell inclusion bodies] (p. 729); rickettsial infections [lymphocytic vasculitis] (p. 671); spider bites (p. 768); papulonecrotic tuberculid (p. 653)

Table 22.1 Histological patterns in infections and infestations—cont'd

Morphological feature	Diseases to be considered
Tissue necrosis	Ecthyma gangrenosum (p. 641); necrotizing fasciitis (p. 644); diphtheria (p. 647); anthrax (p. 663); tularemia (p. 667); cat-scratch disease (p. 668); severe lepra reactional states (p. 662); scrofuloderma (p. 652); <i>Mycobacterium ulcerans</i> infections (p. 654); papulonecrotic tuberculid (p. 653); chancroid [superficial necrosis only] (p. 665); rickettsial infections [eschar present] (p. 671); herpes folliculitis (p. 726); mucormycosis (p. 710); gnat, spider, and beetle bites (p. 768); acute tick bites (p. 768); stonefish and stingray contact (p. 759); orf (p. 722); amebiasis (p. 748)
Epidermal spongiosis	Dermatophytoses (p. 684); candidosis (p. 691); cercarial dermatitis [eosinophils and neutrophils also] (p. 762); larva migrans (p. 765); chigger bites (p. 774); other arthropod bites; contact with moths of the genus <i>Hylesia</i> (p. 778); contact with beetles (p. 778); delayed reactions to cnidarians (p. 758); viral infections, including herpesvirus-6 and coxsackievirus
Intraepidermal vesiculation	Herpes simplex, herpes zoster, and varicella [all three have ballooning degeneration and intranuclear inclusions] (p. 724); orf (p. 722) and milker's nodule (p. 721) [both have pale superficial cytoplasm]; hand, foot, and mouth disease (p. 740); erysipeloid [also superficial dermal edema] (p. 643); beetle bites (p. 778); certain other arthropod bites [may be bullous in hypersensitive persons]; dermatophytoses (p. 684); candidosis (p. 691)
Parasite in tissue sections	Helminth and arthropod infestations; certain injuries from forms of marine life
'Invisible dermatoses' (section stained with H&E appears normal at first glance)	Erythrasma (p. 647); pityriasis versicolor [spores and hyphae are usually easily seen] (p. 695); dermatophytoses [compact orthokeratosis, neutrophils in the stratum corneum or the 'sandwich sign' often present] (p. 687); pitted keratolysis [crateriform defects, pits, or pallor of the stratum corneum are usually obvious, as are bacteria] (p. 648)
Spindle cell pseudotumors	Atypical mycobacteria (p. 654); histoid leprosy (p. 661); acrodermatitis chronica atrophicans (p. 681)

*These infections are more suppurative than granulomatous; the latter component is not always present.
†'Deep fungal infections' is used here to include North American blastomycosis, sporotrichosis, chromomycosis, coccidioidomycosis, paracoccidioidomycosis, subcutaneous phycormycosis, and phaeohyphomycosis.

Bacterial and rickettsial infections

23

Introduction	638	Erosive pustular dermatosis	646	<i>Mycobacterium marinum</i> infection (swimming pool granuloma)	656
Superficial pyogenic infections	638	Blastomycosis-like pyoderma	646	Other nontuberculous (atypical) mycobacteria	656
Impetigo	638	Corynebacterial infections	647	Leprosy	658
Common impetigo	639	Diphtheria	647	Miscellaneous bacterial infections	663
Bullous impetigo	639	Erythrasma	647	Anthrax	663
Staphylococcal 'scalded skin' syndrome (SSSS)	639	Trichomycosis	648	Brucellosis	663
Staphylococcal epidermolytic toxin syndrome	640	Pitted keratolysis	648	Yersiniosis	664
Staphylococcal toxic shock syndrome	640	Neisserial infections	648	Granuloma inguinale	664
Streptococcal toxic shock syndrome	641	Meningococcal infections	648	Chancroid	665
Perianal streptococcal dermatitis	641	Gonococcal infections	649	Rhinoscleroma	666
Ecthyma	641	Mycobacterial infections	650	Tularemia	667
Deep pyogenic infections (cellulitis)	642	Tuberculosis	650	Listeriosis	668

INTRODUCTION

Various bacteria form part of the normal resident flora of the skin. In the past, these organisms were regarded as symbiotic, but there is emerging evidence that these organisms may protect the host; as such, they are mutualistic rather than symbiotic.¹ This subject was reviewed in 2008.¹ In certain circumstances, some of these bacteria may assume pathogenic importance. Other bacteria are present only in pathological circumstances. In this chapter, the following categories of bacterial infections are considered: pyogenic, corynebacterial, neisserial, mycobacterial, miscellaneous, chlamydial, and rickettsial. **Pyogenic infections**, usually caused by *Staphylococcus aureus* and strains of *Streptococcus*, are numerically the most important bacterial infections of the skin. *Staphylococcus aureus*-mediated skin infections require the adherence of the organism to the epidermis, if the skin surface is intact. Following adherence, the organism then invades keratinocytes, resulting in cytokine production and release.² It has been found to induce the expression of tumor necrosis factor- α (TNF- α) in keratinocytes.³ Even exfoliative toxin-negative strains of *Staph. aureus* possess exotoxins capable of disrupting the barrier function of tight junction proteins.⁴ Two distinct groups of pyogenic infection (superficial and deep) can be distinguished on the basis of the anatomical level of involvement of the skin. The pyogenic infections, with the exception of the staphylococcal 'scalded skin' syndrome, which results from the effects of a bacterial exotoxin, are characterized histologically by a heavy infiltrate of neutrophils. These organisms may also infect hair follicles, resulting in folliculitis. Furuncles (see p. 465) are deep-seated acute infections based on the pilosebaceous unit and adjacent dermis. They are of interest because of their association with *Staph. aureus* expressing the Panton-Valentine leukocidin genes.⁵ This strain is found in 42% of isolates from furuncles and in all cases of epidemic furunculosis.⁵

Corynebacterial infections, with the exception of diphtheria, are usually limited to the stratum corneum, and as a consequence, there is no significant inflammatory response: at first glance, the biopsy may appear normal.

Neisserial infections of the skin are rare, although they are an important cause of urethritis. Cutaneous lesions may occur in neisserial septicemias.

Mycobacterial infections usually result in a granulomatous tissue reaction, but this depends on the immune status of the individual, including the development of delayed hypersensitivity. Exceptions include lepromatous leprosy, in which a histiocytic response occurs, and some infections by atypical mycobacteria, in which suppurative granulomas, suppuration, and even nonspecific chronic inflammation may result at various times.

A variety of inflammatory reactions can be seen in the group of **miscellaneous bacterial infections** of the skin. The chapter closes with a brief discussion of chlamydial infections and rickettsial infections. Each group is discussed in turn.

Although they are bacteria, infections by the **actinomycetes** are considered in Chapter 25 (pp. 707–710) because they produce lesions that are clinicopathologically similar in many respects to those produced by some fungi (mycetomas).

Although there are many facets to the defense mechanisms that the body has to various microorganisms, there has been recent interest in toll-like receptors (TLRs) as essential components of the innate immune system.⁶ Each TLR so far recognized binds with specific ligands. For example, TLR-2 predominantly recognizes gram-positive bacterial components.⁶

For some of the diseases that follow, treatment options are considered only briefly or not at all. This is because antibiotic sensitivity of some organisms varies widely from country to country, and cost becomes an additional limiting factor to antibiotic choice in some

communities. Vaccines are currently available for several bacterial diseases, including anthrax, *Haemophilus influenzae*, and *Neisseria meningitidis*.⁷

SUPERFICIAL PYOGENIC INFECTIONS

The superficial pyogenic infections of the skin (pyodermas) include impetigo and its variants and ecthyma. They also include the superficial infections of the hair follicles, which are dealt with in Chapter 15 (pp. 462–465). In addition, the staphylococcal 'scalded skin' syndrome can be included in this category, although the lesions result from the action of bacterial toxin rather than local infection.

IMPETIGO

Impetigo is an acute superficial pyoderma that heals without scar formation. It is the most common bacterial infection of the skin in childhood.^{8–11} Its incidence appears to be increasing.¹² Adults are sometimes affected, particularly athletes, military personnel, and those in institutions.¹³ Minor trauma, especially from insect bites, as well as poor hygiene and a warm, humid climate all predispose to this infection.^{14,15} Seasonal variation in its occurrence has been noted.^{16,17}

There are two clinical forms of impetigo: a common, vesiculopustular type and a bullous variant, which is considerably less frequent.^{18,19} Studies have shown that *Staph. aureus* is now the most common organism isolated from the nonbullous type of impetigo,^{20–22} which in the past was caused mostly by a group A β -hemolytic streptococcus, sometimes with *Staph. aureus* as a secondary invader.^{10,13} Anaerobes are now isolated in a number of cases.²² The bullous form has always been related exclusively to *Staph. aureus*, usually of phage group II.²³ A case of bullous impetigo has been associated with *Abiotrophia defectiva*, a nutritionally variant *Streptococcus* usually associated with endocarditis.²⁴ Both bullous and nonbullous forms of impetigo are associated with exfoliative toxins. Exfoliative toxin genes were present in one study in 100% of *Staph. aureus* isolates from bullous impetigo and from 57% of isolates from nonbullous impetigo.⁵

The incidence of strains of *Staph. aureus* resistant to the antimicrobial agents used in the treatment of impetigo has been increasing; methicillin-resistant *Staph. aureus* (MRSA) accounts for less than 20% of such infections.²⁵ An ointment containing an equal blend of gentamicin and fusidic acid has been widely used in Japan and some European countries to treat localized impetigo.²⁵ Sensitivity to fusidic acid has decreased significantly in recent years.¹⁷ In fact, outbreaks of impetigo caused by fusidic acid-resistant *Staph. aureus* (FRSA) have been reported in areas where fusidic acid is widely used. Significant percentages of FRSA are seen in impetigo patients in these areas, and higher FRSA levels are seen in impetigo than in secondarily infected atopic dermatitis.²⁶ Bacitracin is commonly used, but its efficacy is questionable.²⁷ Topical mupirocin can be an effective treatment option, as are older treatments such as topical gentian violet and vioform.²⁷ Other topical treatments with some benefit include topical hydrogen peroxide cream and also tea lotion and cream.²⁷ Topical retapamulin, which belongs to a new class of antibiotics, is an effective and safe treatment for impetigo.²⁸ Clindamycin has shown excellent activity against most isolates of *Staph. aureus* and can be used for more serious disease. Other antimicrobials that can be used include dicloxacillin, cloxacillin, cephalixin, or amoxicillin combined with potassium clavulanate.²⁷ A recent German study showed that mupirocin, retapamulin, and the antiseptics octenidine and chlorhexidine have a good resistance profile toward tested strains of *Staph. aureus*.²⁹

Common impetigo

Common impetigo ('school sores') commences as thin-walled vesicles or pustules on an erythematous base: the lesions rapidly rupture to form a thick, golden crust.³⁰ Common impetigo occurs as a solitary lesion or a cluster of several lesions, which may coalesce. It is found on the face or extremities.²¹ Local lymphadenopathy may be present.

Some authors use the term impetigo contagiosa (nonbullous impetigo) for this group and restrict the term common impetigo to a secondary impetigo that may complicate systemic disease, or dermatological conditions that cause a break in the skin.²⁷

Bullous impetigo

Bullous impetigo is composed of shallow erosions and flaccid bullae, 0.5–3 cm in diameter, with an erythematous rim.¹³ The bulla has a thin roof that soon ruptures, resulting in a thin crust.²³ There may be a localized collection of a few bullae, or more generalized lesions.^{31,32} Bullous impetigo is included with the staphylococcal epidermolytic toxin syndrome because the lesions result from the production *in situ* of an epidermolytic toxin by staphylococci.¹³

Histopathology

Common impetigo is rarely biopsied because the diagnosis can be made on clinical grounds. An early lesion will show a subcorneal collection of neutrophils, with exocytosis of these cells through the underlying epidermis. A few acantholytic cells are sometimes seen, but this is never a prominent feature. Established lesions show a thick surface crust composed of serum, neutrophils in various stages of breakdown, and some parakeratotic material. Gram-positive cocci can usually be found without difficulty in the surface crust.

In *bullous impetigo*, the subcorneal bulla contains a few acantholytic cells, a small number of neutrophils, and some gram-positive cocci (Fig. 23.1).²³ In contrast to the lesions of the staphylococcal 'scalded skin' syndrome, there is usually a mild to moderate mixed inflammatory cell infiltrate in the underlying papillary dermis.²³

Differential diagnosis

Subcorneal pustule formation can also be identified in subcorneal pustular dermatosis and pemphigus foliaceus. However, the finding of bacteria in a non-eroded vesicopustule points to a diagnosis of impetigo. Pemphigus foliaceus usually shows fewer neutrophils and a greater

degree of acantholysis, often with evidence of dyskeratosis. Pustular psoriasisiform dermatoses, including Reiter's syndrome, candidiasis, and geographic tongue, in addition to psoriasis, ideally show spongiform pustulation in the superficial portions of the spinous layer – a feature not typically seen in impetigo. *Candida* organisms are of course to be expected in the pustular lesions of candidiasis. Immunoglobulin A (IgA) pemphigus of the subcorneal pustular dermatosis type uniquely shows intercellular IgA deposition on direct immunofluorescence examination. Acute generalized exanthematous pustulosis tends to feature smaller superficial pustules and may have the additional changes of apoptosis, underlying leukocytoclastic vasculitis, or a dermal infiltrate that includes eosinophils.

STAPHYLOCOCCAL 'SCALDED SKIN' SYNDROME (SSSS)

The staphylococcal 'scalded skin' syndrome results from the production of an epidermolytic toxin by certain strains of *Staph. aureus*, most notably type 71 of phage group II.^{13,33} Our understanding of these bacterial strains is now much more sophisticated. Exfoliative toxins result from the presence of certain genes – *eta*, *etb*, and *etd* – in the organism. These genes encode for ETA, ETB, and ETD, respectively.⁵ These organisms are responsible for a preceding upper respiratory tract infection, conjunctivitis, or carrier state. Rarely, the syndrome follows a staphylococcal infection complicating varicella or measles.^{34,35}

SSSS predominantly affects healthy infants and children younger than 6 years, apparently reflecting an inability to handle and excrete the toxin.³⁶ Rarely, neonates are involved, a condition known in the past as Ritter's disease (Ritter von Rittershain's disease).³⁷ A few cases have been reported in adults, in whom there has usually been underlying immunosuppression (including AIDS)^{38,39} and/or renal insufficiency.^{40–42} It occurs rarely in healthy adults.^{43–47} There has been a recent report of three older adult patients with osteoarthritis who developed SSSS and septic arthritis following intra-articular corticosteroid injections for osteoarthritis. They did not have histories of renal insufficiency or immunosuppression, but all had received prior treatment with nonsteroidal anti-inflammatory agents, which are known to promote growth of *Staph. aureus* and to diminish renal clearance of toxins.⁴⁸ A similar development occurred in an adult patient who received intra-articular injection of hyaluronic acid, also for osteoarthritis.⁴⁹

There is a sudden onset of skin tenderness and a scarlatiniform eruption that is followed by the development of large, easily ruptured, flaccid bullae and a positive Nikolsky sign.³⁷ Desquamation of large areas of the skin occurs in sheets and ribbons.⁴⁰ Occasionally, only the scarlatiniform eruption develops. A report of five cases suggests that a milder, transient, generalized macular erythema with desquamation limited to body folds and an absence of the Nikolsky sign may be more common than previously thought. In all of these cases, *Staph. aureus* harboring exfoliative toxin genes was isolated, with an absence of super-antigen exotoxin.⁵⁰ The usual sites of involvement are the face, neck, and trunk, including the axillae and groins. Mucous membranes are not involved.

The disease has a good prognosis in children, with spontaneous healing after several days as a consequence of the formation of neutralizing antibodies to the epidermolytic toxin.⁵¹ In adults, a staphylococcal septicemia may ensue and is sometimes fatal. Concurrent SSSS and toxic shock syndrome are extremely rare.⁵² A chronic case, evolving over 2 years, has been reported in an adult female patient.⁵³

Desquamation results from the effects of an exotoxin of low molecular weight (exfoliatin), produced by certain strains of *Staph. aureus*. There are two forms of exfoliatin recognized – exfoliative toxin A (ETA), which is chromosomally encoded, and exfoliative toxin B (ETB), which is plasmid encoded.⁵⁴ Other exfoliative toxins have been

Figure 23.1 Bullous impetigo. There is a subcorneal blister containing inflammatory cells and degenerate keratinocytes. Gram-positive cocci were found. (H&E)

described (ETD).⁵ Exfoliative toxins act as serine proteases that cleave desmoglein 1 in the superficial epidermis.⁵⁵ The condition can be reproduced in newborn mice by the subcutaneous or intraperitoneal injection of these organisms.⁵⁶

The treatment of SSSS involves parenteral antibiotics, such as dicloxacillin, to eradicate the *Staph. aureus*, and appropriate nursing care to prevent the secondary effects of disrupted skin barrier function.³⁹ In general, clindamycin and penicillinase-resistant penicillins⁵⁷ or cephalosporins⁵⁸ have been recommended as initial, empiric therapy until culture and sensitivity data become available.

Staphylococcal epidermolytic toxin syndrome

SSSS, which was historically considered (incorrectly) to be a variant of toxic epidermal necrolysis (see p. 59), has been regarded as belonging to the staphylococcal epidermolytic toxin syndrome.^{59–61} Also included in this concept are localized and generalized bullous impetigo, which result from the local production (as opposed to production at a distant site, as in SSSS) of a similar staphylococcal epidermolytic toxin.³⁴ Consequently, in bullous impetigo, the organisms may be demonstrated within the lesion. Impetigo was previously discussed in further detail.

Histopathology⁶²

In SSSS, there is subcorneal splitting of the epidermis (Fig. 23.2). A few acantholytic cells and sparse neutrophils may be present within the blister, although often it is difficult to obtain an intact lesion. A sparse, mixed inflammatory cell infiltrate is present in the underlying dermis.

Electron microscopy

There is widening of the intercellular spaces followed by disruption of desmosome attachments through their central density.^{13,56} There are no cytotoxic changes.

Differential diagnosis

The lesions must be differentiated from toxic epidermal necrolysis, in which there is full-thickness epidermal necrosis. This differentiation can be made rapidly using frozen sections or rapid processing of exfoliated skin because SSSS shows only superficial epidermal necrosis. Bullous impetigo can often be distinguished from early SSSS because neutrophils are frequently present, organized as subcorneal pustules.

Figure 23.2 The staphylococcal scalded skin syndrome with subcorneal splitting. (H&E)

The separation that occurs in this syndrome is at the same level of the epidermis as pemphigus foliaceus; the exfoliative toxins act on desmoglein 1, the antigenic target of that disorder. However, the sparse, mixed dermal infiltrate of SSSS contrasts with that of pemphigus foliaceus, or even generalized bullous impetigo, in which the dermal infiltrate is heavier. Immunofluorescence is negative, in contrast to pemphigus foliaceus, in which intercellular immunoreactants are usually demonstrable.

STAPHYLOCOCCAL TOXIC SHOCK SYNDROME

The staphylococcal toxic shock syndrome was first recognized more than three decades ago in healthy menstruating women who used tampons.^{63,64} It results from a toxin produced by certain strains of *Staph. aureus* that proliferate in the vagina and cervix. The organisms possess the gene *tst* (toxic shock syndrome toxin gene).⁵ The syndrome may also result from the production of one of the staphylococcal enterotoxins.⁶⁵ These toxins appear to activate T lymphocytes with the production of various cytokines.⁶⁶ The toxic shock syndrome can also complicate wound infections with *Staph. aureus*.⁶⁷ In an epidemiologic study carried out in a metropolitan area of Minnesota covering the years 2000–2006, the average annual incidence per 100,000 population was 0.52 for all toxic shock syndrome cases, with 0.69 for menstrual cases and 0.32 for nonmenstrual cases. The superantigen gene *tst-1* was associated with the majority of menstrual cases, whereas genes *sea*, *seb*, and *sec* were more frequent among nonmenstrual compared to menstrual isolates. MRSA was found in a small percentage of cases.⁶⁸ Currently, the incidence of nonmenstrual disease exceeds that related to the female genital tract.^{33,69} The clinical features of this syndrome include a fever, hypotension, inflammation of mucous membranes, vomiting and diarrhea, and cutaneous lesions that resemble viral exanthemas or erythema multiforme.^{70,71} The skin lesions undergo desquamation in time. The U.S. Centers for Disease Control and Prevention has produced diagnostic criteria for staphylococcal toxic shock syndrome, provided in Table 23.1. Confirmation of the diagnosis requires all of the major criteria and involvement of three or more of seven organ systems.⁷²

In addition, if obtained, there should be negative results from blood, throat, or cerebrospinal fluid cultures for other pathogens (blood cultures may be positive for *Staph. aureus*), and serologic tests for Rocky Mountain spotted fever, leptospirosis, or measles should be negative.

Table 23.1 Clinical criteria for staphylococcal toxic shock syndrome	
Major criteria	Minor criteria
Fever greater than 38.9°C	Central nervous system (disorientation, alterations in consciousness without focal neurological signs in the absence of fever and hypotension)
Diffuse macular erythroderma, with skin desquamation 1–2 weeks after onset of illness, particularly involving palms and soles	Gastrointestinal (vomiting or diarrhea)
Hypotension (systolic blood pressure ≥ 90 mm Hg in adults; less than fifth percentile by age for children younger than 16 years; orthostatic drop in diastolic blood pressure ≥ 15 mm Hg)	Hematologic (platelets $<100,000$ /microliter) Hepatic (bilirubin or transaminases twice upper limit of normal) Mucous membrane hyperemia Muscular (severe myalgia or elevated creatine kinase levels at least twice the upper limit of normal) Renal (urea or creatinine twice upper limit of normal, or pyuria (>5 WBC/hpf))

A streptococcal toxic shock syndrome has also been reported (see later).

Histopathology⁷⁰

The characteristic features of toxic shock syndrome are small foci of epidermal spongiosis containing a few neutrophils, scattered degenerate keratinocytes, sometimes arranged in clusters, and a superficial perivascular and interstitial cell infiltrate.⁷⁰ The infiltrate contains lymphocytes, neutrophils, and sometimes eosinophils.⁷⁰ Inflammatory cells often extend into the walls of the superficial dermal vessels, as seen in vasculitis, but there is no fibrin extravasation. Less constant features include irregular epidermal acanthosis, edema of the papillary dermis, extravasation of erythrocytes, and nuclear 'dust' in the vicinity of the blood vessels.⁷⁰ Focal parakeratosis, containing neutrophils and serum, may also be present.

STREPTOCOCCAL TOXIC SHOCK SYNDROME

The streptococcal toxic shock syndrome is caused by virulent strains of exotoxin-producing streptococci, almost always group A organisms such as *Streptococcus pyogenes*.⁷³ A few cases due to group B streptococci have been reported.⁷⁴ A recent report describes the syndrome in a newborn infant, due to *Streptococcus dysgalactiae* subspecies *equisimilis*, an organism in groups C and G that has shown a high rate of overlap with group A streptococcal genomes.⁷⁵ Two other examples caused by *S. dysgalactiae* subspecies *equisimilis* have been reported in elderly men.^{76,77} It often occurs in the setting of deep soft tissue infections, when the portal of entry of the organism appears to be through the skin, but it may complicate burns, surgical wounds, or childbirth. Accordingly, it can be seen in several clinical situations, such as the young, the immunocompromised, the elderly, and diabetics. Rarely, it has developed in patients taking nonsteroidal anti-inflammatory drugs (NSAIDs).³³

Clinically, there is fever, pain at the site of the deep tissue infection, and skin necrosis and bullae. Renal failure and disseminated intravascular coagulation may occur.⁷⁸ A scarlatiniform rash may be present. A streptococcal bacteremia is present in 60% of cases, in contrast to the usually negative blood cultures in the staphylococcal toxic shock syndrome.⁶⁴ The mortality rate is usually as high as 30%;⁷⁴ it was 62% in a Chinese outbreak in 2005.⁷⁸

Prompt treatment with antibiotics should be undertaken. High-dose penicillin G is usually effective, but antibiotics with a broader spectrum are usually commenced first because the diagnosis may be in doubt.

Histopathology

The changes resemble those in ecthyma gangrenosum (see later). The deep soft tissue lesions, if present, are those of necrotizing fasciitis (see p. 644).

PERIANAL STREPTOCOCCAL DERMATITIS

Perianal streptococcal dermatitis, caused by group A β -hemolytic streptococci, has been described almost exclusively in children, although a few adult cases have been reported.^{79–81} A case due to group G *S. dysgalactiae* subsp. *equisimilis* occurred in an adult male following oral–anal sexual contact.⁸² It presents as perianal erythema with a clearly defined border followed by a desquamating scale and subsequent healing. Systemic symptoms, such as fever, are uncommon,⁸³ in contrast to **toxin-mediated perineal erythema**, which occurs abruptly after a bacterial pharyngitis due to *Staph. aureus* or *S. pyogenes*.^{33,84} It can occur not only in young adults but also in childhood.⁸⁵

ECTHYMA

Ecthyma is a deeper pyoderma than impetigo and much less frequent.¹⁸ It has a predilection for the extremities of children, often at sites of minor trauma, which allow entry of the causative bacteria. Group A streptococci, particularly *S. pyogenes*, are usually implicated, although coagulase-positive staphylococci are sometimes isolated as well.^{19,86} The lesions, which are sometimes multiple, consist of a dark crust adherent to a shallow ulcer and surrounded by a rim of erythema. Scarring usually results when the lesions heal.¹⁹

Ecthyma gangrenosum is a severe variant of ecthyma seen in 5% or more of immunosuppressed individuals who develop a septicemia with *Pseudomonas aeruginosa*.^{87–92} A septicemia is not invariable.⁹³ It has also been seen in a harlequin baby⁹⁴ and in previously healthy individuals.⁹⁵ It commences as an erythematous macule on the trunk or limbs: the lesion rapidly becomes vesicular, then pustular, and finally develops into a gangrenous ulcer with a dark eschar and an erythematous halo.^{96–99} Annular lesions are rare.¹⁰⁰ Periocular lesions have been reported in a diabetic patient.¹⁰¹ Constitutional symptoms are usually present. Patients with solitary lesions have a better prognosis than those with multiple lesions. Similar necrotic ulcers have been reported in association with *Aspergillus*, *Candida*,¹⁰² and *Exserohilum*¹⁰³ infection, *Morganella morganii*,¹⁰⁴ *Citrobacter freundii*,¹⁰⁵ *Chromobacterium violaceum*,¹⁰⁶ candidosis, *Fusarium solani*,¹⁰⁷ MRSA,¹⁰⁸ *Escherichia coli*,¹⁰⁹ and following pseudomonas folliculitis (but usually without septicemia)⁸⁷ and cutaneous infections treated with antibiotics.¹¹⁰ *Pseudomonas aeruginosa* septicemia may result in the development of pustules,¹¹¹ bullae,¹¹² intertrigo,¹¹³ or of a nodular cellulitis¹¹⁴ rather than ecthyma gangrenosum.¹¹⁵ It needs to be distinguished from purpura fulminans in which disseminated intravascular coagulation (DIC) accompanies the infection (see p. 223).^{116–118}

Histopathology

In ecthyma, there is ulceration of the skin with an inflammatory crust on the surface. There is a heavy infiltrate of neutrophils in the reticular dermis, which forms the base of the ulcer (Fig. 23.3). Gram-positive cocci may be seen within the inflammatory crust.

Ecthyma gangrenosum shows necrosis of the epidermis and the upper dermis, with some hemorrhage into the dermis.⁹⁶ The epidermis may separate from the dermis. A mixed inflammatory-cell infiltrate

Figure 23.3 Ecthyma. Ulcer is accompanied by a heavy neutrophilic infiltrate. (H&E)

Figure 23.4 Ecthyma gangrenosum. Numerous bacilli, representing *Pseudomonas* organisms, are present around and within small thrombosed blood vessels in the deep dermis. These prove to be gram-negative with special staining. (H&E)

surrounds the infarcted region. In some cases, there is a paucity of inflammation.^{96,97} A necrotizing vasculitis with vascular thrombosis is present in the margins.¹¹⁴ Numerous gram-negative bacteria are usually present between the collagen bundles, and particularly in the media and adventitia of small blood vessels (Fig. 23.4).

Differential diagnosis

The lesions of ecthyma resemble the excoriations and shallow ulcers that are seen in a variety of pruritic conditions, such as prurigo simplex. The infiltrate-poor vascular changes of ecthyma gangrenosum can also be seen in *Vibrio vulnificus* septicemia. This infection can develop following consumption of raw seafood or through wounds occurring along coastal waters. Indurated plaques and bullae show cutaneous necrosis and connective tissue degeneration with numerous organisms (which, like *Pseudomonas*, are gram-negative bacilli) in the walls of vessels.

DEEP PYOGENIC INFECTIONS (CELLULITIS)

Cellulitis is a diffuse inflammation of the connective tissue of the skin and/or the deeper soft tissues.^{19,119,120} It is therefore a deeper pyoderma than impetigo and some cases of ecthyma, although ecthyma gangrenosum could be included in this category. Clinically, cellulitis presents as an expanding area of erythema, which is usually edematous and tender.¹²¹ Necrosis and hemorrhage sometimes supervene.^{122–125} In the past, these infections were usually caused by β -hemolytic streptococci and/or coagulase-positive staphylococci.^{19,126} A diverse range of organisms is now implicated in the causation of cellulitis.^{119,127–136} The injection of ricin in a suicide attempt resulted in a septic and toxic cellulitis in one patient.¹³⁷ Neutropenic and leukemic patients are now being seen with erythematous nodules on the leg caused by the opportunistic pathogen *Stenotrophomonas* (*Xanthomonas*) *maltophilia*.^{138–140} This organism has also resulted in digital necrosis in an immunocompetent farmer.¹⁴¹ Pyogenic sporotrichoid lymphangitis is a rare presentation.¹⁴² Lower extremity cellulitis appears to be increased in patients who have undergone saphenous venectomy for coronary artery bypass graft surgery,^{143,144} but it is also seen in chronic venous insufficiency and obesity.¹⁴⁵ Gangrenous cheilitis has been reported in a child with

Figure 23.5 Cellulitis. There is a deep dermal-subcutaneous infiltrate composed mainly of neutrophils. (H&E)

myeloperoxidase deficiency.¹⁴⁶ Facial cellulitis may occur secondary to a dental abscess.¹⁴⁷

Many different clinical variants of cellulitis have been reported, some with overlapping clinical features and causative bacteria.¹²¹ This has led to a proliferation of terms for these different variants. The term ‘gangrenous and crepitant cellulitis’ has been used for a subset with prominent skin necrosis and/or the discernible presence of gas in the tissues.^{122,148} The term ‘hemorrhagic cellulitis’ has also been used for this group, which includes progressive bacterial synergistic gangrene. It has been suggested that TNF- α is responsible for the damage to keratinocytes and vascular endothelium.¹⁴⁹ Subcutaneous and/or dermal abscesses are another manifestation of deep infection by various bacteria.^{150–159}

The cellulitides are characterized histopathologically by an infiltrate of neutrophils throughout the dermis and/or the subcutaneous tissue, with variable subepidermal edema and vascular ectasia (Fig. 23.5). In variants with necrosis, there is usually a necrotizing vasculitis, which may be associated with fibrin thrombi in the lumen.^{160,161} Bacteria are often numerous in the group with necrosis, although usually only a few can be isolated in the other variants.¹⁶²

Treatment will usually depend on the antibiotic sensitivity of the causative organism. An increasing problem, of particular interest to dermatologists, is the emergence of community-acquired, methicillin-resistant *Staph. aureus*, which can be highly virulent.^{163–166} This form of infection is now an increasingly common condition among

athletes.¹⁶⁷ It usually presents as skin and soft tissue infections, especially abscesses.¹⁶⁸ Many such abscesses respond to drainage alone, but some will require antibiotic therapy. Trimethoprim-sulfamethoxazole is an inexpensive and effective choice for many such patients.¹⁶⁸ It may be used with rifampin.¹⁶⁹ Resistance is emerging to the fluoroquinolones.¹⁶⁸

ERYSIPELAS

Erysipelas is a distinctive type of cellulitis that has an elevated border and spreads rapidly.^{19,170,171} It is more common in males, and it is most prevalent in patients 65 years or older.¹⁷² Whereas the incidence of bacterial cellulitis of the leg in the United States was reported to be 6.62 per 1000 in 2004, erysipelas was much less common (0.14 per 1000).¹⁷³

Vesiculation may develop, particularly at the edge of the lesion. An uncommon bullous variant, usually confined to the lower legs, has been described.¹⁷⁴ The condition occurs particularly on the lower extremities and less commonly on the face.^{175,176} Underlying diabetes mellitus, peripheral vascular disease, or lymphedema may be present.¹⁷⁵ Erysipelas may complicate the upper limb lymphedema that follows the treatment of breast cancer.¹⁷⁷ The causative group A streptococci,^{120,178} or other organisms,^{179,180} gain entry through superficial abrasions. It is associated with pain, swelling, and fever. Bacteremia is common.¹⁹ Osteoarticular complications are not uncommon.¹⁸¹

An erysipelas-like erythema, usually on the lower legs, is seen in **familial Mediterranean fever**, an autosomal recessive disease affecting certain ethnic groups.¹⁸² The histopathology has features more in keeping with a neutrophilic dermatosis than erysipelas.

The term **pseudoerysipelas** has been given to a recurrent hemolysis-associated erythematous eruption of the lower legs in a patient with hereditary spherocytosis.¹⁸³ No infection was present.¹⁸³

Treatment of erysipelas is usually with β -lactam antibiotics, but macrolides are the second choice.¹⁷² Benzathine penicillin G, intramuscularly at 14-day intervals, has been used as prophylactic antibiotherapy in patients who have experienced recurrent erysipelas in lymphedematous upper limbs following the treatment of breast cancer.¹⁷⁷ Long-standing treatment for lymphedema of the lower limbs is essential in order to prevent recurrence of erysipelas and aggravation of the pre-existing lymphatic impairment.¹⁸⁴

Histopathology

There is marked subepidermal edema, which may lead to the formation of vesiculobullous lesions. Beneath this zone, there is a diffuse and usually heavy infiltrate of neutrophils, but abscesses do not form. Leukocytoclasia can usually be found.¹⁸⁵ The infiltrate is sometimes accentuated around blood vessels. There is often vascular and lymphatic dilatation. In healing lesions, the dermal infiltrate diminishes, and granulation tissue may form immediately below the zone of subepidermal edema (Fig. 23.6). Direct immunofluorescence has been used to confirm the streptococcal etiology of most cases of erysipelas.¹⁷⁸

Differential diagnosis

Histopathologic evaluation is not always carried out in cases of erysipelas (or cellulitis), and when carried out, it generally provides only supportive rather than independently diagnostic information. The finding of neutrophils in the dermis in the absence of an obvious source, such as ulceration, ruptured follicles or cysts, or leukocytoclastic vasculitis, should always raise the possibility of infection and prompt cultures or other laboratory studies. The neutrophilic infiltrate in Sweet's syndrome is much heavier than in erysipelas or cellulitis, tends to be concentrated in the mid dermis (although subcutaneous infiltration can definitely occur in that disease), and is associated with

leukocytoclasia. Rheumatoid disease can be accompanied by cutaneous neutrophilic infiltrates, two examples being rheumatoid neutrophilic dermatosis and interstitial granulomatous dermatitis (the latter is not restricted to rheumatoid disease and can be seen in a wide variety of connective tissue, inflammatory, and infectious processes). The density of neutrophils in rheumatoid neutrophilic dermatosis and the presence of interstitial granulomas in interstitial granulomatous dermatitis would be distinctive. α_1 -Antitrypsin deficiency panniculitis can be preceded or accompanied by deep dermal neutrophils that 'splay' the collagen bundles, but there are characteristic degenerative and necrotizing changes in the subcutis that set that process apart. There are some microscopic differences between true erysipelas and the erysipelas-like erythema that accompanies familial Mediterranean fever. In contrast to erysipelas, erysipelas-like erythema has a milder inflammatory infiltrate, is less likely to have an interstitial component to the infiltrate, includes mononuclear cells as well as neutrophils, may or may not demonstrate leukocytoclasia, and shows absent or only mild papillary dermal edema.¹⁸⁵

ERYSIPELOID

Erysipeloid is an uncommon infection, usually found on the hands, which clinically resembles erysipelas.¹⁸⁶ The causative organism, *Erysipelothrix rhusiopathiae*, is a contaminant of dead organic matter, and infection with this organism is an occupational hazard for fish and meat handlers.¹⁸⁷ The incubation period varies from 1 to 7 days after inoculation.¹⁸⁸ Less commonly, multiple cutaneous lesions or systemic spread of the organism may occur. A recent case of erysipeloid of 1-year duration presented as macrocheilitis; microscopic examination showed non-caseating granulomas.¹⁸⁹ Erysipeloid-like eruptions have been reported in several patients receiving chemotherapy with gemcitabine.¹⁹⁰

Treatment of erysipeloid with penicillin for 7–10 days results in dramatic improvement.^{187,188}

Histopathology¹⁸⁶

There is usually massive edema of the papillary dermis overlying a diffuse and polymorphous infiltrate composed of lymphocytes, plasma cells, and variable numbers of neutrophils. Sometimes there is spongiosis of the epidermis, leading to intraepidermal vesiculation. Organisms are not demonstrable in tissue sections, even with a Gram stain, possibly because they are present in the L form (without a cell wall).¹⁸⁶ A case developing in an immunocompromised child showed epidermal necrosis, a suppurative infiltrate in the dermis extending into the subcutis, and, with Gram stain, aggregates of gram-positive bacilli in the upper reticular dermis.¹⁹¹

BLISTERING DISTAL DACTYLITIS

Blistering distal dactylitis is an uncommon but distinctive infection localized to the volar fat pad of the distal phalanx of the fingers.^{19,192–195} Group A streptococci are usually implicated, although rarely other organisms have been isolated,^{196,197} including a case caused by MRSA in a 6-month-old infant.¹⁹⁸ The blistering results from massive subepidermal edema.

CELLULITIS

In addition to its use as a synonym for deep pyogenic infection (discussed previously), the term 'cellulitis' is sometimes used in a more restricted sense for spreading inflammation of the cheek,^{199–201} periorbital area^{202,203} or the perianal region,^{194,204–207} or in the margins of wounds¹⁹ or injecting sites.²⁰⁸ The lesions lack the distinct border of erysipelas.¹⁹ Various organisms have been implicated as the cause of

Figure 23.6 Erysipelas. (A) Acute lesion with marked subepidermal edema. (B) This healing lesion shows little inflammation in the upper dermis. (H&E)

this condition,²⁰⁹ including *Staph. aureus* in patients with HIV infection,²¹⁰ community-associated MRSA (causing orbital cellulitis),^{211,212} *H. influenzae* type b in the case of facial lesions,^{200,213} and *V. vulnificus* in some infections of the extremities.^{214–221} The latter organism can produce various lesions, including septicemia, hemorrhagic bullae,^{222,223} cellulitis, and necrotizing fasciitis.²²⁴ *Pasteurella multocida* has been implicated in the wound infection and cellulitis that may follow animal bites.²²⁵ *Vibrio cholerae* (non-01 type) can rarely produce a cellulitis or infect a pre-existing wound.^{226,227} *Escherichia coli* has also been implicated, particularly in immunocompromised individuals.^{228,229} Varicella infection is complicated, rarely, by a cellulitis resulting from group A β -hemolytic streptococci or *Staph. aureus*.²³⁰ A case of neonatal streptococcal cellulitis, with sepsis, was apparently acquired from the mother's mild skin infection. It was caused by group A *Streptococcus*, emm type 53.2.²³¹ Cellulitis caused by group B²³² and group C²³³ streptococci has also been reported.

Histopathology

The appearances are similar to those of erysipelas; focal necrosis is sometimes present. Involvement of the subcutis may lead to a predominantly septal panniculitis.^{160,214}

NECROTIZING FASCIITIS

Necrotizing fasciitis is a rare and distinct form of cellulitis that rapidly progresses to necrosis of the skin and underlying tissues.^{234–242} It occurs mostly in adults, but cases in children have been reported.²⁴³ The term 'flesh-eating bacteria' has appeared in the media, highlighting the progressive necrotizing nature of the disease.²⁴⁴ It involves tissues at a deeper level than erysipelas, and it may spread into the underlying muscle.²⁴⁵ Necrotizing fasciitis commences as a poorly defined area of erythema, usually on the leg,²³⁴ or perineal region.²⁴⁶ Bilateral periorbital involvement has been recorded.²⁴⁷ Serosanguineous blisters develop, and subsequently necrosis occurs at their center.^{248,249} It often follows a penetrating injury. Uncommonly, the condition follows surgery;²⁵⁰ in one case, it followed mosquito bites.²⁵¹ There may be underlying diabetes, alcoholism, or some other immune system deficiency.^{252,253} There is a strong association with the use of NSAIDs.²⁵⁴ It may occur in intravenous drug users.^{255,256} Constitutional symptoms may be present, and there is a significant mortality rate.²⁴⁵ The term 'streptococcal toxic shock syndrome' has been applied to this systemic illness,²⁵⁷ although it more properly refers to a discrete entity with some similarity to the toxic shock syndrome of staphylococcal origin

(see p. 641).³³ Various organisms have been isolated,^{258–260} particularly group A streptococci.^{249,261–263} Examples have been caused by *C. violaceum*,²⁶⁴ *Serratia marcescens*,²⁶⁵ and *V. vulnificus*.²⁶⁶ Often, the infection is polymicrobial.^{243,267} A zygomycete has also been isolated from this condition.²⁶⁸ Rapid diagnosis kits are available to confirm cases of streptococcal origin. Protein S deficiency may be responsible for the necrosis in some cases.²⁶⁹ Several scoring systems have been developed to enhance the clinical diagnosis of this condition, including the Laboratory Risk Indicator for Necrotizing Fasciitis (LRINEC) and the Acute Physiology and Chronic Health Evaluation (APACHE II).^{270,271} The development of systemic lupus erythematosus immediately following necrotizing fasciitis has been reported, which is an example of postinfection autoimmunity.²⁷²

Immediate treatment of necrotizing fasciitis with penicillin, if group A streptococci are involved, or with clindamycin plus cefoperazone sodium, if the organism is not known, is recommended once a diagnosis is made, together with surgical debridement.²⁴³ The antibiotics should then be tailored to the sensitivity of any organism(s) cultured.²⁶²

Fournier's gangrene of the scrotum is a closely related entity.^{248,273} It is usually found in elderly men, with an underlying disease such as diabetes. Cases have been reported in younger persons.²⁷⁴ It is a rare complication of the use of all-*trans*-retinoic acid as induction therapy in the treatment of acute promyelocytic leukemia. Its response to corticosteroids suggests that Fournier's gangrene is a localized vasculitis and represents a local Schwartzmann phenomenon.²⁷⁵ Enterobacteria are common isolates, although a mixed growth is often seen.^{276,277} In one series, the mortality rate was nearly 10%.²⁷⁶ Treatment of Fournier's gangrene includes fluid resuscitation, empirical broad-spectrum antibiotics until the antibiotic sensitivities of the organism(s) are known, and surgical debridement of necrotic tissue.²⁷³

Histopathology^{234,235}

Necrotizing fasciitis is a form of septic vasculitis with inflammation of the walls of vessels, sometimes associated with occlusion of the lumen by thrombi.¹⁶¹ There is a mixed inflammatory cell infiltrate in the viable tissues bordering the areas of necrosis. The necrosis involves the epidermis, dermis, and upper subcutis (Fig. 23.7).

Differential diagnosis

The depth of involvement, as well as the degree of connective tissue degeneration and necrosis, is much greater in necrotizing fasciitis than in erysipelas or traditional forms of cellulitis. Necrosis and connective tissue degeneration are also seen in forms of ischemia, including calciphylaxis and bullae related to coma or barbiturate intoxication, but these conditions lack the neutrophilic infiltration of necrotizing fasciitis, and Gram stains and tissue culture studies are typically negative. The clinical distinction between necrotizing fasciitis and pyoderma gangrenosum can sometimes be difficult.²⁷⁸ The microscopic differential diagnosis is discussed in Chapter 8. In summary, pyoderma gangrenosum beyond early stages tends to show subepidermal edema and undermining inflammation at the ulcer border. Although there can be extension of inflammation into the subcutis, deep vessel thrombosis is not a characteristic feature of pyoderma gangrenosum. The granulomas seen in some examples of pyoderma gangrenosum would also argue against necrotizing fasciitis, as of course would negative blood and tissue culture studies. A case of **thrombophilia** mimicking necrotizing fasciitis has been reported. Edema, purpura, and blisters were among the clinical features, although the patient was not pyrexial, appeared systemically well, and the affected areas in many cases were cooler than adjacent, uninvolved skin. Biopsy showed epidermal necrosis, subepidermal bullae, and dermal edema with hemorrhage and necrosis. However, despite thrombosis of small vessels, inflammation was mild,

Figure 23.7 Necrotizing fasciitis. (A) Inflammation, some degree of cell necrosis, and thrombosis are present in this example. (B) There is sweat gland necrosis with neutrophilic infiltration. (H&E)

and special stains and cultures were negative for organisms. Predisposing factors for thrombosis in this patient included heterozygosity for the factor V Leiden mutation (resulting in resistance to activated protein C) and her pregnancy status at the time of presentation.²⁷⁹ Another condition that can be difficult to distinguish from necrotizing fasciitis is the uncommon necrotizing variant of Sweet's syndrome, recently described in three immunocompromised patients.²⁸⁰ All patients had a hematologic malignancy and had been administered granulocyte colony-stimulating factor – known risk factors for Sweet's syndrome. All had demonstrable pathergy. Microscopically, acute inflammation involved the subcutis and fascia, associated with fat necrosis and significant myonecrosis. Differentiating features include negative Gram staining in Sweet's syndrome and, surprisingly, the presence of myonecrosis because this tends to occur only in late-stage lesions of necrotizing fasciitis, by which point necrosis can be discerned to some degree in all tissue layers.²⁸⁰ It is possible that the thrombosis seen in necrotizing fasciitis may constitute an additional distinguishing characteristic.

MISCELLANEOUS SYNDROMES

There are several rare but distinct clinicopathological entities that belong to the category of deep pyogenic infections. They include clostridial myonecrosis (gas gangrene), progressive bacterial synergistic gangrene, and erosive pustular dermatosis of the scalp, legs, and other sites. They are discussed in turn.

Clostridial myonecrosis (gas gangrene)

Clostridial myonecrosis (gas gangrene) is associated with muscle and soft tissue necrosis. Cutaneous lesions, including bullae and necrosis, may overlie the deeper lesions. The usual causative organisms in gas gangrene are clostridial species; nonclostridial cases are infrequently reported.²⁸¹ Wound botulism has been reported in black tar heroin users.^{122,282} A bacterium related to the genus *Clostridium* – *Bacillus piliformis* – has produced localized verrucous lesions in a patient infected with HIV-1.²⁸³ *Bacillus cereus* infection has been associated with a single necrotic bulla in a patient with a lymphoma.²⁸⁴

Treatment includes the immediate surgical debridement of damaged tissue and the use of antibiotics such as penicillin in high doses. Hyperbaric oxygen therapy is also effective, but it should not delay the other measures already mentioned.

Histopathology

Findings include necrosis and degenerative changes of subcutaneous tissue, fat, and muscle with an absence of inflammatory cells in the involved areas, although neutrophils can be found along the endothelia of small vessels.²⁸⁵ Large gram-positive bacilli are usually present in the affected tissues.

Progressive bacterial synergistic gangrene

Progressive bacterial synergistic gangrene is characterized by indurated ulcerated areas with a gangrenous margin, usually developing in operative wounds.^{122,286} This condition, also known as Meleney's ulcer, is often associated with a mixed growth of peptostreptococci and *Staph. aureus* or enterobacteriaceae.¹²²

Erosive pustular dermatosis

Erosive pustular dermatosis is an uncommon disorder of the elderly that involves predominantly the sun-damaged scalp. It presents with widespread erosions and crusted sterile pustules, leading to scarring alopecia.^{287–289} Intact pustules are rarely present, despite the name.²⁹⁰ A clinically similar rash has been reported on the legs, particularly in a background of chronic venous stasis.^{290–292} Lesions on the face and other body sites have also been reported, and it has been suggested that chronic, nonhealing, shallow erosions on actinically damaged or otherwise atrophic skin are related conditions. The condition has a female predominance, and most affected individuals are older than age 65 years; it has also been reported in a 15-year-old boy²⁹⁰ and in infants.²⁹³

Its exact nosological position is uncertain, but there are some morphological similarities to blastomycosis-like pyoderma (discussed later). Trauma, previous herpes zoster infection, recent cryotherapy, 5-fluorouracil application, topical imiquimod treatment for actinic keratoses,²⁹⁴ topical minoxidil solution,²⁹⁵ radiation therapy, and surgery have all been implicated as predisposing factors.^{290,296–301} Cases in infants may follow perinatal scalp injury.²⁹³ *Staphylococcus aureus* is sometimes isolated, but these organisms may be secondary invaders.²⁸⁷ **Amicrobial pustulosis associated with autoimmune diseases** is probably part of

the spectrum. It may involve the scalp as well as the flexures. It has responded to zinc therapy.³⁰²

Treatment with potent topical corticosteroids is frequently used. Topical tacrolimus ointment and calcipotriol (calcipotriene) cream can also be used. Oral zinc sulfate and isotretinoin have been tried in some cases,^{303–305} and photodynamic therapy has been used successfully,^{306,307} although there is also a report of erosive pustular dermatosis development following photodynamic therapy for actinic keratoses on the scalp.³⁰⁸ The lesions do not respond to topical or oral antibiotics.²⁹³

Histopathology

The skin is usually ulcerated, but intact atrophic epidermis may cover other involved areas. In such cases, there is exocytosis of inflammatory cells. There is variable crusting overlying ulcerated skin and atrophic areas. Intact pustules are rarely seen; in one case, the pustule was subcorneal, with focal spongiform pustulation.³⁰⁹ The dermal infiltrate is moderate to marked, and it consists of lymphocytes and variable numbers of plasma cells. Erythematous papules have shown perifollicular neutrophilic and eosinophilic infiltrates.³¹⁰ Granulation tissue has also been described.³¹¹ Scarring is progressive. There may be a few foreign body giant cells in areas of follicular destruction.³⁰³

BLASTOMYCOSIS-LIKE PYODERMA

Blastomycosis-like pyoderma is an unusual form of pyoderma that presents with large verrucous plaques studded with multiple pustules and draining sinuses.^{312,313} There may be an underlying disturbance of immunological function in some cases.^{313,314} A variant of this condition is found in subtropical areas of Australia in the actinically damaged skin of the elderly, particularly on the forearm.^{315,316} This has been known as 'coral reef granuloma', on the basis of its clinical appearance.³¹⁷ Actinic comedonal plaque, in which plaques and nodules with a cribriform appearance develop in sun-damaged skin,³¹⁸ appears to be the end stage of a similar but milder inflammatory process.^{315,316} Similar lesions have been reported at the margins of tattoos.^{315,319} Actinic comedonal plaque has also been regarded as an ectopic form of the Favre–Racouchot syndrome (see p. 394).³²⁰

Bacteria, particularly *Staph. aureus* and species of *Pseudomonas* and *Proteus*, have been isolated from biopsies.^{313,315,321,322} One case was caused by a mixed infection consisting of *Staph. epidermidis* and *Trichophyton rubrum*.³²³ Sun-damaged skin is known to diminish local immune responses, and this factor is probably important in the variant found in Australia.^{324,325}

Response to antibiotics such as oral doxycycline is often poor, despite *in vitro* susceptibility of the organism to tetracyclines.³²⁶ Minocycline has also been used. Local ablative measures such as curettage and cautery, carbon dioxide laser, or cryotherapy may be used if surgical excision is unsuitable.³²⁷ Low-dose oral acitretin for 3 or 4 months has been used successfully.³²⁶

Histopathology

There is a heavy inflammatory infiltrate throughout the dermis, with multiple small abscesses set in a background of chronic inflammation (Fig. 23.8).³¹³ A few granulomas are occasionally present, but these are usually related to elastotic fibers. There is prominent pseudoepitheliomatous hyperplasia, which in some areas appears to result from hypertrophy of the follicular infundibulum. Intraepidermal microabscesses are present, and these probably represent the attempted trans-epidermal elimination of the dermal inflammatory process. Solar elastotic fibers are present in the variants known as 'coral reef

Figure 23.8 Blastomycosis-like pyoderma. (A) There is dermal suppuration adjacent to enlarged follicular structures that become draining sinuses. (B) Suppurative granulomas are often present. (H&E)

granuloma' and 'actinic comedonal plaque'.³¹⁸ There may be some dermal fibrosis in healing lesions, although actinically damaged fibers usually persist in the upper dermis.

CORYNEBACTERIAL INFECTIONS

The corynebacteria are a diverse group of gram-positive bacilli that include *Corynebacterium diphtheriae*, the causative organism of diphtheria, as well as a bewildering number of species that are found on the skin as part of the normal flora and that defy classification.³²⁸ These latter organisms are usually referred to as diphtheroids or coryneforms. Certain strains have the ability to produce malodor of the axilla.³²⁹ Three skin conditions appear to be related to an overabundance of these coryneforms: erythrasma, trichomycosis, and pitted keratolysis.³²⁸ Interestingly, the three have been reported to coexist in some individuals.^{330,331} Rarely, other species of corynebacteria have been incriminated as a source of infection in diabetics³³² or immunocompromised patients, the most important being the JK group (*Corynebacterium jeikeium*).^{333,334} These organisms have been found in patients with heart prostheses and endocarditis and also as a cause of cutaneous lesions in immunocompromised patients.³³³

They may produce a histological picture mimicking botryomycosis (see p. 710).³³⁴

Topical sodium fucidate has been used to treat cutaneous disease.³³¹ Oral erythromycin can be used for more extensive infections.³³¹

DIPHTHERIA

Cutaneous diphtheria is a rarely diagnosed entity that is still found very occasionally in tropical areas.^{335–337} Cases have been reported in travelers to western Africa³³⁸ and Indonesia,³³⁹ but it has also been reported in New Zealand,^{340,341} in Germany (associated with occupational pig contact),³⁴² and among the urban poor in Vancouver, British Columbia.³⁴³ The typical lesion is an ulcer with a well-defined irregular margin; the base is covered with a gray slough. Systemic effects, from the absorption of exotoxin, and severe lymphadenitis may develop. Cutaneous carriers also occur.

The treatment of diphtheria requires the administration of a specific antitoxin as soon as the diagnosis is made and also the use of penicillin or erythromycin.

Histopathology

There is necrosis of the epidermis and varying depths of the dermis. The base of the ulcer is composed of necrotic debris, fibrin, and a mixed inflammatory infiltrate. The bacilli are often difficult to see in tissue sections.

ERYTHRASMA

Erythrasma, caused by a diphtheroid bacillus *Corynebacterium minutissimum* (although other species of *Corynebacterium* have also been reported),³⁴⁴ presents as well-defined, red to brown finely scaling patches with a predilection for skin folds, particularly the inner aspect of the thigh just below the crural fold.^{345–347} A rare generalized disciform variant has been reported.³⁴⁷ This organism has been cultured from granulomatous nodules on the leg in an HIV-infected male.³⁴⁸ Erythrasma is a not uncommon asymptomatic infection in the obese, and in diabetics and patients in institutions, particularly in humid climates.^{345,346} Examination of affected skin under a Wood's ultraviolet lamp shows a characteristic coral-red fluorescence (because of the presence of porphyrins). In a case of erythrasma due to *Corynebacterium aurimucosum* and *Microbacterium oxydans*, analysis demonstrated elevated levels of coproporphyrin III.³⁴⁴

Erythrasma may coexist with a dermatophyte infection, particularly in the toe webs.^{349,350}

The treatment of erythrasma involves the topical application of one of the imidazole antifungal agents, such as clotrimazole, ketoconazole, or miconazole. Whitfield's ointment has been used for interdigital lesions. Erythromycin can be used for extensive or recurrent cases.

Histopathology

The biopsy often appears normal when hematoxylin and eosin (H&E) preparations are examined, with erythrasma being an example of a so-called 'invisible dermatosis'. Small coccobacilli can be seen in the superficial part of the stratum corneum in Gram preparations and sometimes in H&E-stained sections (Fig. 23.9A). They are also seen in periodic acid-Schiff (PAS) and methenamine silver preparations (Fig. 23.9B).

Electron microscopy

Electron microscopy has confirmed the bacterial nature of erythrasma. It has also shown decreased electron density in keratinized cells, with dissolution of normal keratin fibrils at sites of proliferation of organisms.^{351,352}

Figure 23.9 Erythrasma. (A) An unusually large number of organisms are seen in the stratum corneum in this example. (H&E) (B) Minute organisms can be seen in the stratum corneum. There is no inflammatory response. (Periodic acid-Schiff)

TRICHOMYCOSIS

Trichomycosis is a bacterial infection of axillary hair (trichomycosis axillaris) and, uncommonly, pubic hair (trichomycosis pubis).^{353,354} It has also been reported in the intergluteal region, eyebrows,³⁵⁵ and scalp.³⁵⁶ There are usually pale yellow concretions attached to the hair shaft: these are large bacterial colonies. Sometimes the casts are red, and rarely they are black.³⁵⁴ They may be the source of an offensive odor. The causative organism was originally designated as *Corynebacterium tenuis*, but it now seems that at least three species are involved.^{354,357} The infecting bacteria are generally believed to produce a cement-like substance that they use to adhere to the hair shaft and to form the large concretions,³⁵⁴ this traditional view has been challenged,³⁵⁸ and it has been suggested that the sheath substance in which the organisms are embedded is apocrine sweat.³⁵⁸ Sometimes the bacteria invade the superficial hair cortex;³⁵⁹ this has been demonstrated with scanning electron microscopy.³⁵⁶ A yellow fluorescence has been demonstrated with Wood's light examination.³⁵⁵ Trichomycosis must be distinguished from other extraneous substances attached to the hair shaft.

The use of an antiperspirant will usually control the disease. If there is a heavy growth of organisms on the hairs, clipping followed by the application of a topical antibacterial agent will hasten resolution.

PITTED KERATOLYSIS

Pitted keratolysis is characterized by multiple asymptomatic pits and superficial erosions on the plantar surface of the feet, particularly in pressure areas.^{360–365} Rarely, the palms are involved.^{361,366,367} It occurs predominantly in young adults; there is a male predominance.³⁶⁸ Sometimes there is brownish discoloration of involved areas, giving them a dirt-impregnated appearance.³⁶⁹ Pitted keratolysis is more common if the feet are moist from hyperhidrosis or because the climate is hot.³⁷⁰ It is often associated with the wearing of occlusive and protective shoes.³⁶⁸ Malodor is common.³⁶⁵ The pits are thought to result from the keratolytic activity of species of *Corynebacterium*, but *Dermatophilus congolensis*^{362,371} and *Micrococcus sedentarius*³⁷² have also been incriminated.

As with erythrasma, the topical application of one of the imidazole antifungal agents is usually effective. Fucidin ointment has also been used. Any excess sweating should be appropriately controlled.

Histopathology^{361,369}

Microscopically, the pits appear as multiple crateriform defects in the stratum corneum. In early lesions, there are areas of pallor within the stratum corneum (Fig. 23.10). In the base and margins of the pits, there are fine filamentous and coccoid organisms that are gram positive and argyrophilic with the methenamine silver stain. It has been suggested that two types of pitted keratolysis can be distinguished histologically.³⁷³ In the superficial or minor type, there is only a small depression due to focal lysis. Coccoid bacteria are found on the surface of the stratum corneum. In the classic or major type, the organisms exhibit dimorphism with septate 'hyphae' as well as coccoid forms, which extend into the stratum corneum forming more definite pits.³⁷³

Dermoscopy has shown irregular shapes and sizes of the pit walls, presumably due to the random nature of stratum corneum dissolution.³⁷⁴

Electron microscopy

Ultrastructural examination has confirmed the great variability in the morphology of the bacteria, with coccoid, diphtheroid, and filamentous forms in the stratum corneum.³⁶⁰

Tunnel-like spaces form inside the horny layer, where the bacteria have a 'hairy' surface.³⁷⁵

NEISSERIAL INFECTIONS

Primary infections of the skin by *Neisseria meningitidis* and *N. gonorrhoeae* are rare because these organisms are unable to penetrate intact epidermis. However, cutaneous lesions do occur quite commonly in meningococcal and gonococcal septicemia; they take the form of a vasculitis (see Chapter 8, p. 239).

MENINGOCOCCAL INFECTIONS

Cutaneous lesions, which may take the form of erythematous macules, nodules, petechiae, or small pustules, occur in 80% or more of acute meningococcal infections (see p. 239). Features of disseminated intravascular coagulation are invariably present. Chronic meningococcal septicemia is comparatively rare; it is characterized by the triad of intermittent fever, arthralgia, and vesiculopustular or hemorrhagic

Figure 23.10 Pitted keratolysis. (A) The stratum corneum adjacent to an area of pitting shows zones of pallor corresponding to foci containing the causative organisms. (H&E) (B) They can be seen in the pale areas of the stratum corneum using silver stains. (Silver methenamine)

Figure 23.11 Chronic meningococcemia. There is leukocytoclastic vasculitis, composed mainly of neutrophils with a complement of lymphocytes. (H&E)

lesions of the skin. The hemorrhagic lesions are usually a manifestation of purpura fulminans, which develops in 15–25% of those with meningococcemia.³⁷⁶ It is a predictor of poor outcome.³⁷⁶ Chronic meningococcemia is a rare complication in patients with AIDS.³⁷⁷ A *N. meningitidis*-specific polymerase chain reaction (PCR) assay is available for testing skin biopsy specimens in suspected chronic meningococcemia.³⁷⁸

Histopathology

The cutaneous lesions in meningococcal septicemia show an acute vasculitis, with fibrin thrombi in the small blood vessels of the dermis and extravasation of fibrin. There are neutrophils in and around the vessels, but the infiltrate is not as heavy as it is in hypersensitivity vasculitis. Leukocytoclasia is not usually a conspicuous feature.

In pustular lesions of chronic meningococcemia, there are intraepidermal and subepidermal collections of neutrophils. A vasculitis is present in the dermis; the infiltrate contains some lymphocytes in addition to neutrophils (Fig. 23.11).

GONOCOCCAL INFECTIONS

Urethritis (gonorrhea) is the usual manifestation of infection with *N. gonorrhoeae*. There is now a high incidence of this disease among HIV-infected men who have sex with men.³⁷⁹ This sexually transmitted disease may also infect the accessory glands of the vulva and the median raphe of the penis.³⁸⁰ Primary infections of extragenital skin are very rare, although pustular lesions on the digits have been reported.³⁸¹ Cases of non-gonococcal urethritis due to species of *Mycoplasma* are not uncommon. The macrolide antibiotics appear to be more effective than tetracyclines in this group of infections.³⁸²

Gonococcal septicemia, both acute and chronic, may result in a cutaneous vasculitis; the lesions resemble those seen in meningococcal septicemia (discussed previously).^{383,384}

First-line treatment for gonorrhea depends very much on the antibiotic susceptibility of the organism, in a particular region. In areas of Europe, resistance to ciprofloxacin exceeds 50%.³⁸⁵ Antibiotics such as cefixime, ceftriaxone, spectinomycin, and, in some cases, azithromycin or ciprofloxacin have been used.³⁸⁵

Figure 23.12 Gonococcemia. (A) There is a thrombosed vessel in the mid dermis. (B) Within the thrombus, diplococci can be identified (arrows). (Tissue Gram stain)

Histopathology

Primary pustular lesions on the penis or extragenital skin are usually ulcerated, with a heavy inflammatory cell infiltrate in the underlying dermis. There are numerous neutrophils, often forming small abscesses. Gram-negative intracellular diplococci can usually be found in tissue sections, but they are more easily found in smears made from the purulent exudate on the surface of the lesion.

In gonococcal septicemia, the cutaneous lesions resemble those seen in meningococcal septicemia (discussed previously); the appearances are those of a septic vasculitis (see Fig. 8.12; Fig. 23.12).

MYCOBACTERIAL INFECTIONS

The cutaneous mycobacterioses include leprosy and tuberculosis, as well as a diverse group of infections caused by various environmental (atypical, nontuberculous) mycobacteria. Within these three categories, there are clinicopathological variants that are sometimes given the status of distinct entities; for example, infections by *Mycobacterium ulcerans* and *M. marinum* (Buruli ulcer and swimming pool granuloma, respectively) are often considered separately from infections caused by other nontuberculous (atypical) mycobacteria.

Established mycobacterial infections generally give rise to a granulomatous tissue reaction, although considerable variability exists in the histopathological appearances of individual lesions.³⁸⁶ These aspects are considered further later.

TUBERCULOSIS

Tuberculosis of the skin has been declining in incidence throughout the world, although it is still an important infective disorder in India and areas of Africa.^{387–391} The epidemic of HIV/AIDS in areas of Africa has been followed by an epidemic of tuberculosis in its wake.³⁹² It has been estimated that nearly 8 million new cases of tuberculosis occur in the world each year.³⁹³ Cutaneous tuberculosis is a relatively rare manifestation of tuberculosis, accounting for only 0.14% of all reported cases.³⁹⁴ With the eradication of tuberculosis in cattle, human infections with *Mycobacterium bovis* are rarely seen these days,^{395–397} although this continues to be a problem in the United Kingdom.³⁹⁸ Accordingly, cutaneous tuberculosis can be categorized into two major etiological groups: infections caused by *Mycobacterium tuberculosis* and those caused by nontuberculous (atypical) mycobacteria. Infections by nontuberculous mycobacteria are considered separately. In some of the so-called ‘developed countries’, such infections are more numerous than those caused by *M. tuberculosis*.

Not all individuals exposed to *M. tuberculosis* become infected. There is a complex interaction between the organism, the environment, and the host.³⁹⁹ Corticosteroids may upset this balance, leading to the reactivation of non-active disease.⁴⁰⁰ The increasing use of biological therapies for the treatment of inflammatory skin diseases, particularly psoriasis, has also led to an increase in tuberculosis.⁴⁰¹ Genetic susceptibility to *M. tuberculosis* (OMIM 607948) involves many genes. One such gene maps to chromosome 2q35, which includes the *NRAMP1* gene (natural resistance-associated macrophage protein 1),³⁹⁹ and the *MTBS1* gene. Another TB susceptibility locus is found at chromosome 8q12–q13. X-linked susceptibility has also been proposed. Patients with hypomorphic mutations of the nuclear factor κ B essential modulator gene may also have increased susceptibility to mycobacterial disease.⁴⁰² A review on the genetically determined susceptibility to mycobacterial infection was published in 2008.⁴⁰³ The review discussed in detail the genetic abnormalities in the interleukin 12 (IL-12)-dependent, high-output interferon- γ (IFN- γ) pathway that result in increased susceptibility to infection.⁴⁰³

Polymorphisms LTA(+368) and IL-10(–592) in linkage disequilibrium may affect susceptibility to forms of tuberculosis in a Peruvian population,⁴⁰⁴ whereas polymorphisms of the IL-12-IFNG pathway may play a similar role in pulmonary tuberculosis in China.⁴⁰⁵ Several studies have shown that genetic variants of the *MARCO* gene (macrophage receptor with a collagenous structure) may be associated with susceptibility to pulmonary tuberculosis in both Chinese and Gambian populations; this is an essential factor for toll-like receptor signaling in the macrophagic response to *M. tuberculosis*.^{406,407} Polymorphism in an inflammasome gene, *CARD8* (caspase recruitment domain-containing protein 8), appears to be associated with HIV and *M. tuberculosis* co-infection.⁴⁰⁸ A cautionary note regarding these types of studies has been expressed in a paper by Stein, based on variations in study design with regard to definition of phenotype, handling of cases of latent *M. tuberculosis* infection versus active disease, population substructure and linkage disequilibrium, and other factors.⁴⁰⁹

Classification

Infections with *M. tuberculosis* have traditionally been classified into primary tuberculosis, when there has been no previous exposure to the organism, and secondary tuberculosis, resulting from reinfection with the tubercle bacillus.³⁸⁷ Reinfection (secondary) tuberculosis of the skin is subdivided on the basis of various clinical features into lupus

vulgaris, tuberculosis verrucosa cutis, scrofuloderma, orificial tuberculosis, and disseminated cutaneous tuberculosis.⁴¹⁰ The tuberculids are a further category and were thought to represent a cutaneous reaction to a tuberculous infection elsewhere in the body, there being no detectable bacilli in the tuberculid skin lesions by conventional techniques.

This traditional classification has been disparaged somewhat, and a classification based on the presumed route of infection has been proposed.^{411,412} Several modifications have already been suggested, but its basic format remains as follows:^{413–415}

- Infections due to inoculation from an *exogenous* source
- Infections from an *endogenous* source, both contiguous (scrofuloderma in the traditional classification) and from autoinoculation (orificial tuberculosis)
- Infections resulting from *hematogenous* spread.

The last of these three categories can be further subdivided into lupus vulgaris, acute disseminated tuberculosis, and the formation of cutaneous nodules or abscesses.

This relatively new system of classification has the advantage of applying to infections with atypical mycobacteria as well as those caused by *M. tuberculosis*. However, it still requires assumptions to be made when an attempt is made to classify an individual case. Furthermore, because infections with certain atypical mycobacteria (Buruli ulcer and swimming pool granuloma) are established clinical entities, it seems unlikely that this new classification will offer many advantages over the traditional one. Such has been the case. It should also be emphasized that cases occur that defy classification by any means, and it is quite appropriate to diagnose ‘cutaneous tuberculosis’ in these cases, pending the completion of cultural identification (if obtained).^{410,416} Various automated techniques, using PCR, now provide a rapid and specific method for the identification of *M. tuberculosis* from tissue samples.^{417–423} However, despite general enthusiasm for this technique,^{424–431} several studies have concluded that PCR was not of much use in paucibacillary forms of cutaneous tuberculosis, particularly using paraffin-embedded tissue.^{432,433} Two commercially available interferon- γ release assays (IGRAs) are now being used in place of tuberculin skin tests for the detection of asymptomatic infections.⁴³⁴ *Mycobacterium tuberculosis* has also been identified by PCR in some cases of sarcoidosis.⁴³⁵

Any classification of cutaneous tuberculosis should also make provision for the complications of bacillus Calmette–Guérin (BCG) vaccination.⁴³⁶ These include local abscesses and secondary bacterial infections, lupus vulgaris,^{437–439} lymphadenitis, lichen scrofulosorum,⁴⁴⁰ and other tuberculids,⁴⁴¹ scrofuloderma-like lesions,^{442,443} and local keloid formation.⁴⁴⁴ Granulomatous nodules have developed at the injection site following a long period of latency.^{445,446} Fatalities have been recorded following BCG vaccination of individuals who are immunocompromised and develop disseminated disease.^{447–452} There is also a genetic predisposition to disseminated disease following BCG vaccination. It is closely related to the genetic abnormalities associated with atypical mycobacteriosis (see later).

The histological pattern of the BCG test site may be erythema multiforme-like, basal spongiotic in type, or have a nonspecific perivascular infiltrate of lymphocytes. If active tuberculosis is present, the test site frequently has the more severe erythema multiforme-type reaction, sometimes with bulla formation.⁴⁵³

Of interest is the use of polyclonal anti-*M. bovis* antibodies to detect bacterial and fungal microorganisms in paraffin-embedded tissue.⁴⁵⁴ This technique is particularly useful in cases with only small numbers of organisms.

The following classification is followed here:

- Primary tuberculosis
- Lupus vulgaris

- Tuberculosis verrucosa
- Scrofuloderma
- Orificial tuberculosis
- Disseminated cutaneous tuberculosis
- Tuberculids.

In a series of 153 cases with cutaneous tuberculosis reported from Pakistan, 41.2% had lupus vulgaris, 35.3% scrofuloderma (mainly children), and 19% tuberculosis verrucosa.⁴⁵⁵

The treatment of cutaneous tuberculosis usually involves the concurrent use of four drugs – isoniazid, rifampicin, pyrazinamide, and either ethambutol or streptomycin – for a period of 8 weeks.^{415,456,457} This quadruple therapy is followed by a 16-week course of isoniazid and rifampicin. There can be variations in these schedules.^{458–460} Pyridoxine is sometimes added to prevent the neurotoxicity of isoniazid.⁴⁶¹ Drug-resistant strains are becoming more frequent. Tuberculosis resistant to first-line drugs can be managed with ethambutol, ofloxacin, and thioacetazone.⁴⁶² Because there is sometimes difficulty in making and/or confirming the diagnosis of cutaneous tuberculosis, a therapeutic trial of antituberculous therapy is sometimes commenced; 6 weeks of therapy with three or four antituberculous drugs is considered adequate to prove or disprove the diagnosis.⁴⁶³

Primary tuberculosis

Primary (inoculation) tuberculosis of the skin is the cutaneous analogue of the pulmonary Ghon focus.^{464,465} One to three weeks after introduction of the organism by way of a penetrating injury, a red indurated papule appears.^{466–472} This subsequently ulcerates, forming a so-called ‘tuberculoid chancre’. Ulcerated lesions may also be a manifestation of secondary (reinfection) tuberculosis,⁴⁷³ when the source of infection may be endogenous or from inoculation, although secondary inoculation tuberculosis usually presents as tuberculosis verrucosa (see later).⁴⁷⁴ Sporotrichoid lesions have developed following a primary inoculation lesion.⁴⁷⁵ Regional lymphadenopathy usually develops in primary tuberculosis.

Primary tuberculosis may be associated with tattooing,^{461,466} ritual circumcision, nose piercing,⁴⁷⁶ inoculation of homeopathic solutions,⁴⁷⁷ or injury by contaminated objects⁴⁷⁸ to laboratory workers, surgeons, or prosectors.^{464,479,480} Sometimes no obvious source of infection can be identified, particularly in children.^{481,482} Atypical (nontuberculous) mycobacteria are now implicated more often than *M. tuberculosis* in the etiology of primary tuberculous infection of the skin.

Histopathology⁴⁶⁴

Early lesions show a mixed dermal infiltrate of neutrophils, lymphocytes, and plasma cells. This is followed by superficial necrosis and ulceration. After some weeks, tuberculoid granulomas form, and these may be accompanied by caseation necrosis.⁴¹⁰ Acid-fast bacilli are usually easy to find in the early lesions, but there are very few bacilli once granulomas develop.

Lupus vulgaris

Lupus vulgaris is the most common form of reinfection tuberculosis, occurring predominantly in young adults.^{483,484} There is one report of its occurrence in siblings.⁴⁸⁵ It is caused almost exclusively by *M. tuberculosis*, although rare reports implicating the *M. avium–intracellulare* complex, *M. fortuitum*,⁴⁸⁶ and *M. bovis* have been published.^{395,487–489} It has followed BCG vaccination^{439,456,490,491} and also tattoo inoculation.⁴⁹² Lupus vulgaris affects primarily the head and neck region,⁴⁹³ although in Southeast Asia it appears to be more common on the extremities and buttocks.^{494–497} Penile involvement can occur.⁴⁹⁸ Lesions involving the nose and face can be destructive. Alopecia often develops in lesions of the scalp.⁴⁹⁹ The usual picture is of multiple

erythematous papules forming a plaque, which on diascopy shows small ‘apple jelly’ nodules.^{500,501} Crusted ulcers, local cellulitis,⁵⁰² sporotrichoid lesions,^{503,504} ‘turkey-ear’ lesions,⁵⁰⁵ and dry verrucous plaques are sometimes seen.⁴⁹⁴ It may develop within a scar⁵⁰⁶ or following tattooing.⁵⁰⁷ Disseminated lesions have been reported.^{508,509} Annular lesions resembling tinea cruris have been reported in an Asian patient.⁵¹⁰ The disease runs a chronic course and may result in significant scarring. Late complications include the development of contractures, lymphedema, squamous carcinoma^{386,411,511–514} (including a case of verrucous carcinoma),⁵¹⁵ and, rarely, basal cell carcinoma,⁵¹⁶ malignant melanoma,⁵¹⁷ and cutaneous lymphomas.^{518,519}

Histopathology⁴⁹⁴

In lupus vulgaris, there are tuberculoid granulomas with a variable mantle of lymphocytes in the upper and mid dermis.⁴⁸³ The granulomas have a tendency to confluence (Fig. 23.13). Rarely, they have a perifollicular arrangement.⁵²⁰ Caseation is sometimes present. If prominent caseation is present in a facial lesion, granulomatous rosacea also needs consideration.⁵²¹ Multinucleate giant cells are not always numerous. Langerhans cells are present in moderate numbers in the granulomas.⁵²² The overlying epidermis may be atrophic or hyperplastic, but only

Figure 23.13 Lupus vulgaris. There are tuberculoid granulomas, with a tendency to confluence, throughout the dermis. (H&E)

rarely is there pseudoepitheliomatous hyperplasia. Transepidermal elimination of granulomas through a hyperplastic epidermis is rarely seen.⁵²³ Bacilli are usually sparse and difficult to demonstrate in sections stained to show acid-fast organisms.⁵¹⁸ They can now be demonstrated using PCR.^{524,525} In one report, Michaelis–Gutmann bodies were present in macrophages in the infiltrate.⁵²⁶ Variable fibrosis accompanies the lesions. Effective antituberculous therapy leads to a substantial reduction of fibrosis.⁵²⁷

Sometimes the histological appearances resemble sarcoidosis, with only a relatively sparse lymphocytic mantle around the granulomas: a consequent delay in making the correct diagnosis is common in such cases.^{411,458,528}

An atypical CD30⁺ lymphoid infiltrate has also been described. The infiltrate was eventually regarded as being of reactive type.⁵²⁹

Differential diagnosis

The histopathologic differential diagnosis can include granulomatous infiltrates of a variety of types, including those of other infectious diseases, such as atypical mycobacterioses, sarcoidosis, and granulomas of the foreign body type. Lupus vulgaris in regions other than the head and neck can create particular diagnostic difficulties. This is illustrated by a recent case of a patient with jaundice, abdominal pain, and perianal and peristomal plaques; initial biopsies suggested Crohn’s disease, but this was not supported by colonoscopy and mucosal biopsies, while tissue cultures eventually proved to be positive for *M. tuberculosis*.⁵³⁰ Erythematous, macular variants of this condition, termed lupus vulgaris erythematosus by Darier, can be misdiagnosed as eczematous dermatitis or other conditions – a problem made worse by the paucibacillary nature of these lesions, which only occasionally show mycobacteria on special staining.⁵³¹ In these circumstances, more sensitive testing (e.g., immunohistochemical staining for mycobacteria, the fluorescent auramine-rhodamine method (Truant stain), PCR techniques, or culture studies) is warranted, indicating that a high index of suspicion is necessary in such cases.

Tuberculosis verrucosa cutis

Tuberculosis verrucosa is an uncommon form of cutaneous tuberculosis resulting from inoculation of organisms into the skin in individuals with good immunity.^{532–534} It may occur as an occupational hazard in the autopsy room. A verrucous plaque forms on the back of the hand, elbows, or fingers.^{410,459,535–537} The lower extremities are more often involved in cases occurring in India and Hong Kong.^{387,538–543} A paradoxical response can occur in 10–15% of patients with tuberculosis, including those with tuberculosis verrucosa cutis, while on antituberculosis therapy. This consists of initial improvement followed by a flare of existing lesions or development of new lesions. This is believed to result from a hypersensitivity reaction to tuberculo proteins released by dead organisms.⁵⁴⁴

Histopathology⁵³⁵

There is hyperkeratosis and hyperplasia of the epidermis, often of pseudoepitheliomatous proportions (Fig. 23.14). In the mid dermis, there are caseating granulomas.³⁸⁸ Acid-fast bacilli can usually be found on careful examination of tissue sections.

Scrofuloderma

Scrofuloderma is tuberculous involvement of the skin resulting from direct extension from an underlying tuberculous lesion in lymph nodes or bone.^{388,460,545–548} The term has also been used, incorrectly, for cases with presumptive cutaneous inoculation.⁵⁴⁹ The neck and submandibular region are the most common sites.^{550–553} Scrofuloderma usually presents as an undermined ulcer or discharging sinus, with surrounding

Figure 23.14 Tuberculosis verrucosa cutis. There are pseudoepitheliomatous hyperplasia and an acute and granulomatous dermal infiltrate. (H&E)

Figure 23.15 Scrofuloderma. There is a large area of caseation necrosis, surrounded by a lymphocytic and granulomatous infiltrate. (H&E)

induration and dusky red discoloration.^{388,410,554,555} Sporotrichoid lesions were present in one case.⁵⁰⁴ Internal organs are often involved in this form of the disease.⁴⁵⁷ In contrast, patients with organ tuberculosis uncommonly have cutaneous disease.^{556,557} Nontuberculous (atypical) mycobacteria are often responsible for this type of infection. It has been reported following BCG vaccination.^{442,443}

Histopathology³⁸⁸

The epidermis is usually atrophic or ulcerated, with an underlying abscess and/or caseation necrosis involving the dermis and subcutis.⁴¹⁰ At the periphery of the necrotic tissue, there are granulomas (Fig. 23.15). They have fewer lymphocytes than is usual in tuberculosis, suggesting a weak cell-mediated immune response.⁵⁵⁸ Acid-fast bacilli can usually be found in smears taken from the affected area, although they are not always demonstrable in tissue sections.³⁸⁸

Orificial tuberculosis (tuberculosis cutis orificialis)

Orificial tuberculosis is a rare form of cutaneous tuberculosis that presents as shallow ulcers at mucocutaneous junctions in patients with

advanced internal (usually pulmonary) tuberculosis.^{420,559–561} It results from autoinoculation.⁵⁶² Perianal tuberculosis is a rare variant of orificial tuberculosis.^{563–565}

Histopathology

There is ulceration with underlying caseating granulomas and numerous acid-fast bacilli.

Disseminated cutaneous tuberculosis

Disseminated cutaneous tuberculosis results from the dissemination of tubercle bacilli from pulmonary, meningeal, or other tuberculous foci,⁵⁶⁶ particularly in children.^{551,567,568} There may be an underlying disturbance of the immune system predisposing to this widespread infection.⁵⁶⁹ The usual presentation is with papules, pustules, vesicles, and abscesses that become necrotic, forming small ulcers.^{394,410,569–571} Disseminated infection in patients with AIDS may take the form of multiple small pustules³⁹⁷ or erythematous papules.⁵⁷² As such, the cutaneous lesions may be a manifestation of more widespread miliary tuberculosis.⁵⁷³

Histopathology⁵⁷⁴

In early lesions, there is focal necrosis and abscess formation, with numerous acid-fast bacilli, surrounded by a zone of nonspecific chronic inflammation.^{410,569} In older lesions, granulomas usually develop in this outer zone. In the pustular lesions seen in patients with AIDS, there are numerous neutrophils in the papillary dermis, with rare Langhans giant cells.³⁹⁷ Noncaseating granulomas were described in another case that developed in a renal transplant patient; many acid-fast bacilli were identified in sections from the lesion.⁵⁷⁵

Tuberculids

Tuberculids are a heterogeneous group of cutaneous lesions that occur in association with tuberculous infections elsewhere in the body, or in other parts of the skin,^{387,576–578} in patients with a high degree of immunity and allergic sensitivity to the organism.⁵⁷⁹ Nevertheless, rare cases have been reported in patients with HIV infection.⁵⁸⁰ Tuberculids may act as sentinel lesions of visceral tuberculosis, and their presence should initiate a search for overt or occult disease.⁵⁸¹ Tuberculids have also followed BCG vaccination.⁴⁴¹ Tuberculids are increasing in incidence in some countries.⁵⁸² Bacteria cannot be isolated from tuberculids, although *M. tuberculosis* DNA can be demonstrated in some cases using PCR.^{583,584} IGRAs (discussed previously) have also detected latent tuberculous infection in tuberculids.⁴³⁴ Response to antituberculous therapy has been recorded even in some cases in which no bacterial DNA could be detected.

Occasionally, the concept of tuberculids has been challenged, but they are usually considered to include erythema induratum–nodular vasculitis, lichen scrofulosorum, papulonecrotic tuberculid, and nodular tuberculid.^{413,415} Granulomatous phlebitis is possibly a fifth type (phlebitic tuberculid),^{585,586} although there are some similarities to nodular tuberculid. More than one type of tuberculid is sometimes present,^{587,588} and transformation from one type into another has been recorded.⁵⁸⁹ Sometimes the tuberculid does not fit neatly into one of the current categories. One such case resembled generalized granuloma annulare.⁵⁹⁰

Erythema induratum–nodular vasculitis

This is a panniculitis (see p. 535) that presents with bluish-red plaques and nodules, with a predilection for the lower part of the legs, particularly the calves.^{591,592} The coexistence of this condition and papulonecrotic tuberculid has been reported.⁵⁹³ *Mycobacterium tuberculosis* DNA has been recovered from lesional skin using a PCR technique.⁵⁹⁴

Lichen scrofulosorum

This tuberculid is characterized by asymptomatic, slightly scaly papules measuring 0.5–3 mm in diameter.^{595–600} They are often follicular in distribution, mainly affecting the trunk of children and young adults.^{596,601} One case had a clinical resemblance to lichen planus,⁶⁰² whereas another had inflammatory pustular lesions resembling psoriasis.⁶⁰³ Localization to the vulva is a rare event.^{604,605} Lichen scrofulosorum usually occurs in association with tuberculosis of bone or of lymph nodes, but it may be associated with tuberculous infection in other sites,^{595,596,606,607} rarely it may follow BCG vaccination⁴⁴⁰ or infection with *M. avium*^{608,609} or other nontuberculous mycobacteria.⁶¹⁰ It sometimes appears during treatment of tuberculosis.⁶¹¹

Papulonecrotic tuberculid

This presents as dusky papules or nodules that sometimes undergo central necrosis and that leave varioliform scars on healing.^{612–615} There is a predilection for the extremities, although the ears and genital region may also be involved.^{616–619} A variant with verrucous lesions mimicking Kyrle's disease has been described.⁶²⁰ It is uncommon in children.⁶¹⁹ In one study, a focus of tuberculosis was identified elsewhere in the body in 38% of cases.^{591,622,623} The tuberculin test is usually strongly positive, and the lesions respond to antituberculous drugs. Multidrug-resistant strains of tuberculosis have been encountered.⁶²⁴ In a number of cases, *M. tuberculosis* DNA can be demonstrated in lesional skin by PCR.^{621,625} Nontuberculous (atypical) mycobacteria have also been implicated.^{626,627}

Nodular tuberculid

In nodular tuberculid, there are dusky-red, nontender nodules on the skin.^{415,576,628} Similar nodules and cord-like thickenings of the superficial veins occur on the lower leg in phlebitic tuberculid.^{629,630}

Histopathology

Erythema induratum–nodular vasculitis is a lobular panniculitis. It is not possible to diagnose which cases are due to tuberculosis on the histology alone (see p. 535). Traditionally, erythema induratum has been distinguished from nodular vasculitis on the basis of more prominent necrosis of the fat lobules and the extension of tuberculoid granulomas into the lower dermis.

Lichen scrofulosorum is characterized by noncaseating tuberculoid granulomas in the upper dermis,⁶³¹ the lesions have a perifollicular and eccrine localization.⁵⁹⁶ Bacilli are not demonstrable.

Papulonecrotic tuberculid exhibits ulceration and V-shaped areas of necrosis, which include a variable thickness of dermis and the overlying epidermis. There is a surrounding palisade of histiocytes and chronic inflammatory cells and also an occasional well-formed granuloma.^{612,621} Vessels in the vicinity show disruption and fibrinoid necrosis of their walls, sometimes with accompanying thrombosis or vasculitis.^{396,632} Follicular necrosis or suppuration is present in approximately 20% of cases.⁶¹³ No bacilli can be demonstrated using routine staining methods.⁶¹²

In *nodular tuberculid*, granulomatous inflammation is located at the junction of the subcutaneous fat and the lower dermis. It involves the walls of arterioles.⁶²⁸

INFECTIONS BY NONTUBERCULOUS (ATYPICAL) MYCOBACTERIA

The nontuberculous (atypical, environmental) mycobacteria are a heterogeneous group of acid-fast bacteria that differ from *M. tuberculosis* in their clinical and cultural characteristics, as well as in their sensitivities to the various antimycobacterial drugs.^{633,634} The traditional Runyon

classification of the nontuberculous (atypical) mycobacteria, which is based on colonial pigmentation, morphology, and growth characteristics, is of no relevance to dermatopathology.

Familial atypical mycobacteriosis (OMIM 209950) is a rare syndrome due to a constellation of genetic abnormalities, some of which have involved only a few families. The genes involved include the IFN- γ receptor-1 and -2 genes (*IFNGR1* and *IFNGR2*, respectively), the β_1 chain of the IL-12 receptor (*IL12RB1*) gene, and the *STAT-1* gene.⁶³⁵

Nontuberculous (atypical) mycobacteria can cause infections in the lungs, lymph nodes, meninges, synovium, and skin.^{633,636,637} Cervicofacial lymphadenitis due to nontuberculous mycobacteria is not uncommon in children.⁶³⁸ Two species, *M. ulcerans* and *M. marinum*, result in well-defined clinicopathological entities known respectively as Buruli ulcer and swimming pool (fish tank) granuloma. They merit individual consideration. Cutaneous infections are rarely produced by the other nontuberculous (atypical) mycobacteria; when they occur, they are associated with a diversity of clinical and histopathological appearances that are not species specific.^{386,639} Accordingly, they are considered together after discussion of *M. ulcerans* and *M. marinum* infections.

The treatment of *M. ulcerans* and *M. marinum* infections of the skin is discussed under those sections (see later). The treatment of other nontuberculous mycobacteria should be based on the antibiotic susceptibility results for the organism being treated. Clarithromycin is suitable for *M. abscessus*, *M. goodii*, *M. xenopi*, *M. scrofulaceum*, and *M. fortuitum*.^{640,641} In the case of *M. chelonae*, linezolid is sometimes added.⁶⁴² High levels of resistance to many antimycobacterial drugs are now being seen with *M. chelonae* infections.^{643,644} Amikacin is also used with clarithromycin for this organism because the use of two drugs reduces the incidence of drug-resistant strains.⁶⁴⁵ Levofloxacin has been used for drug-resistant *M. fortuitum* infections, again with amikacin.^{646,647} Imipenem, quinolones, and sulfonamides are other drugs that can be used for this species.^{647,648} For *M. haemophilum* infections, ciprofloxacin, clarithromycin, rifampicin, imipenem, and sulfamethoxazole have been used as monotherapy or in dual combinations.⁶⁴⁹

Mycobacterium ulcerans infection (Buruli ulcer)

Infections with *M. ulcerans* (Buruli ulcer, Bairnsdale ulcer) have been reported from many areas of Central and West Africa,^{650,651} as well as from New Guinea, Australia,⁶⁵² Southeast Asia,⁶⁵³ Mexico, and Japan, where the causative agent is *M. ulcerans* subsp. *shinshuense*, an organism with slight genetic differences.⁶⁵⁴ The natural reservoir of the organism and the mode of transmission are unknown,⁶⁵⁵ although current evidence suggests that infection is acquired through abraded skin after contact with contaminated water, soil, or vegetation.^{651,656} The organism has been identified by PCR in several cases of sea-urchin granulomas.⁶⁵⁷ *Mycobacterium ulcerans* DNA has been found in water and material in swamps, mosquitos, aquatic plants, crustaceans, molluscs, and small fish.⁶⁵⁸ However, mammals may also serve as a reservoir, in that positive results have been obtained from various species of possums in an endemic area of Victoria, Australia.⁶⁵⁸ The organism grows preferentially at 32° or 33°C and produces an exotoxin, mycolactone, which is responsible for tissue necrosis.⁶⁵⁵ Recent studies suggest that all mycolactone-producing mycobacteria, including *M. ulcerans*, may have derived from a common *M. marinum* progenitor and have adapted to specific environments in which certain attributes, including slow growth and production of an immune suppressor, have conferred a survival advantage.⁶⁵⁹ PCR testing can be used in tracing the source of the infection by means of a DNA fingerprinting method.⁶⁶⁰

Mycobacterium ulcerans produces lesions that predominantly involve the skin and subcutaneous fat and, less commonly, the underlying fascia, muscle, and, rarely, bone. Systemic spread is exceedingly rare.⁶⁶¹ The initial lesion is usually a papule or pustule on the

extremities, particularly on the lower part of the legs. Ulceration soon develops and may extend quite rapidly. The ulcer is painless and has a characteristic undermined edge.⁶⁶² Satellite lesions may develop.⁶⁵⁵ Affected individuals are usually children or young adults.⁶⁵¹ Patients with HIV infection may have aggressive infection.⁶⁶³ Delay in presentation and time to diagnosis is often prolonged in non-endemic areas.⁶⁶⁴ The necrosis associated with this lesion is probably caused by mycolactone,⁶⁶⁵ which can be detected in tissues infected with *M. ulcerans*.⁶⁶⁶ Mycolactone suppresses components of cell-mediated immunity, including macrophages, monocytes, and B and T lymphocytes, partly by inhibiting production of interleukins, TNF- α , and IFN- γ .⁶⁶⁷

A consensus conference held in 2006 recommended surgical excision with a small rim of normal tissue as the treatment of choice.⁶⁶⁸ Antibiotics play a role in countries in which surgery is not readily available and also in extensive disease. The World Health Organization (WHO) recommends the combination of oral rifampin (rifampicin) and parenteral streptomycin for initial treatment. Clarithromycin or ciprofloxacin may be added.⁶⁶⁸ Treatment failure is less common if antibiotics are combined with surgery.⁶⁶⁹

As with other mycobacterial infections, including tuberculosis and leprosy (see previous section on tuberculosis verrucosa cutis), a

paradoxical reaction related to organism killing can occur during therapy, manifested as clinical worsening following initial improvement. This has been called the immune reconstitution inflammatory syndrome (IRIS),⁶⁷⁰ and it is particularly seen in HIV⁺ patients following the initiation of anti-retroviral therapy, although it also occurs in immunocompetent individuals. Cutaneous manifestations of these paradoxical reactions include flares of existing lesions, development of new lesions, increased drainage from lesions, and formation of necrotic eschars. Corticosteroid therapy is useful in the management of these paradoxical reactions.⁶⁷⁰

Histopathology^{652,671}

The most striking feature is extensive 'coagulative' necrosis involving the dermis and subcutaneous fat, with remarkably little cellular infiltration (Fig. 23.16). A septolobular panniculitis is present in some areas. In the viable margins, there is a mixed inflammatory cell infiltrate. The epidermis at the margins of the ulceration shows variable changes; pseudoepitheliomatous hyperplasia may sometimes be present.⁶⁷² There is sometimes a vasculitis involving small vessels in the septa of the subcutaneous fat adjacent to areas of fat necrosis. There are usually

Figure 23.16 *Mycobacterium ulcerans*. (A) There is necrosis of the dermis with peripheral extension beyond the limits of the surface ulceration (so-called 'undermining'). An epidermal downgrowth is present at the edge of the ulcer. (B) There is suppurative and necrotic changes in the subcutis. (H&E)

numerous clumps of acid-fast bacilli, sometimes forming globular structures, in the necrotic tissue. These organisms are extracellular in location.

In long-standing or recurrent lesions, there is usually a granulomatous response, although the granulomas are poorly defined. Caseation is absent. Organisms tend to be sparse in these lesions. Calcification sometimes occurs in the necrotic tissues in cases of long standing.⁶⁷³ Biopsies of lesions undergoing paradoxical reactions show granulation tissue with mixed inflammation, including multinucleated giant cells; rare acid-fast bacilli can sometimes be identified with Fite staining.⁶⁷⁰

Fine needle aspiration has been shown to be a simple, relatively painless, and accurate method of sampling for the diagnosis of *M. ulcerans* infection by PCR methodology, particularly in early stage, non-ulcerative lesions.⁶⁷⁴

A loop-mediated isothermal amplification (LAMP) technique, a rapid single tube method of amplifying DNA, has been developed for use in diagnosing Buruli ulcer. Primer sets have been used that target the mycolactone-encoding plasmid genome sequence of *M. ulcerans*. The advantages of this method are that it is highly specific and easier, cheaper, and much more sensitive than existing PCR methods.^{675,676}

Differential diagnosis

The necrotizing and degenerative appearance of *M. ulcerans* infections must be distinguished from toxin-mediated lesions, such as spider bites, or from the degenerative changes produced by vascular occlusion (e.g., due to calciphylaxis or antiphospholipid antibodies) or ischemia (e.g., coma bullae). Spider bites, however, show accompanying inflammation, including eosinophils. Thrombosed or calcified vessels provide a clue to other possible causes of tissue degeneration and necrosis, but it must be noted that intimal thickening and occlusion of small arteries have been identified in the periphery of lesions due to *M. ulcerans*. Because numerous organisms can be identified in *M. ulcerans* lesions at this stage of the infection, special staining (i.e., Fite stain) can be decisive, and therefore an index of suspicion for mycobacterial infection must be maintained in such cases.

Mycobacterium marinum infection (swimming pool granuloma)

Mycobacterium marinum is a nontuberculous (environmental, atypical) mycobacterium that has its natural habitat in brackish water, swimming pools, and aquarium tanks.^{677–680} In some areas, it is the most common mycobacterial infection.⁶⁸¹ Because it is unable to multiply at the temperature of the internal organs, the lesions that result from infection by it are usually confined to the skin. Involvement of the synovium and of the larynx⁶⁸² has been reported.

The cutaneous lesions are usually solitary verrucoid nodules or plaques on the elbows, hands, or knees that develop 1 or 2 weeks after superficial trauma, usually sustained in an aquatic environment.^{683,684} Laboratory inoculation has also been reported.⁶⁸⁵ Lesions may persist for months or years if untreated. Such cases have been seen among South Pacific Islanders, in whom untreated lesions have developed into extensive warty and ulcerated plaques.⁶⁸⁶ Sometimes, in the so-called 'sporotrichoid' form of infection, there are multiple lesions along the course of the main superficial lymphatic vessels, reminiscent of the ascending lymphangitis of sporotrichosis.^{677,687–690} Sporotrichoid lesions have been reported in a patient with Crohn's disease receiving infliximab.⁶⁹¹ More extensive cutaneous involvement has been reported in immunosuppressed individuals^{681,692} and in a child.^{693,694} Simultaneous infection with *Nocardia asteroides* has also been reported.⁶⁹⁵

The second-generation tetracyclines, particularly minocycline, are frequently used to treat *M. marinum* infections.⁶⁹⁶ Newer fluoroquinolones, including sparfloxacin, and moxifloxacin have also been used.

In a report of 16 patients with *M. marinum* infections, the macrolide antibiotic clarithromycin was effective in all cases.⁶⁴⁰

Histopathology^{697–699}

The inflammatory process is usually confined to the dermis, although in the sporotrichoid form subcutaneous involvement is more common. The changes are quite variable, ranging from a mostly acute process with suppuration to granuloma formation.⁶⁹⁹ Early lesion can be quite neutrophilic. The granulomas are usually poorly formed; there is no evidence of caseation. Some neutrophils may be admixed, in places forming suppurative granulomas. A chronic inflammatory cell infiltrate is present between the granulomas and foci of suppuration. Rarely, the pattern may simulate interstitial granuloma annulare.⁷⁰⁰ Epidermal changes are variable and include ulceration, acanthosis, and sometimes even pseudoepitheliomatous hyperplasia (Fig. 23.17). Lichenoid changes were present in one case resulting in a lichenoid and granulomatous dermatitis.⁷⁰¹

Acid-fast bacilli are found in a minority of cases.⁶⁹⁷ The organisms tend to be longer and fatter than *M. tuberculosis*, and sometimes they show transverse bands.⁶⁷⁸ Rarely, organisms are abundant.⁶⁹⁸ Isolation of the organism is readily achieved in culture at 30–33°C. PCR-based methods are now being used to confirm the diagnosis.⁶⁸⁹ One of these involves examination of the *hsp65* gene.⁷⁰²

Differential diagnosis

For *M. marinum* infection, a major differential diagnostic consideration is sporotrichosis because there can be considerable clinical and histopathologic overlap of these infections. This is particularly the case when ascending sporotrichoid nodules are encountered in the former. Because in both infections organisms may be difficult to identify with special staining, culture studies and PCR methods are often of great importance.

Other nontuberculous (atypical) mycobacteria

There is a miscellaneous group of nontuberculous (atypical) mycobacteria. The *M. fortuitum* complex (*M. fortuitum* group and *M. chelonae/abscessus* group) account for the majority of skin and soft tissue infections in the United States.⁶⁴⁷ They produce a diverse range of cutaneous lesions,⁷⁰³ including solitary verrucous nodules,⁷⁰⁴ erythematous nodules,⁶⁴⁸ ulcers,^{705–707} furuncles,⁶⁴⁷ abscesses,⁷⁰⁸ cellulitis,⁷⁰⁹ rosacea-like lesions,⁷¹⁰ disseminated suppurative panniculitis,⁷¹¹ spindle cell pseudotumors,^{665,712–714} acne conglobata-like lesions,⁷¹⁵ and sporotrichoid nodules.^{716–720} Infection may follow minor trauma,⁷²¹ injections,⁷²² including mesotherapy and acupuncture,^{645,723,724} body piercing,⁷²⁵ tattooing,^{726,727} biopsy and surgical procedures,^{728–730} and the implantation of prostheses, or occur in immunosuppressed individuals.^{703,708,731,732} The species involved include *M. kansasii*,^{472,627,708,709,732–738} *M. haemophilum*,^{739–746} *M. scrofulaceum*,^{641,747} *M. szulgai*,^{718,748,749} *M. xenopi*,⁶⁴⁰ *M. neoaurum*,⁷⁵⁰ *M. gordonae*,^{640,704,712,751,752} the *M. avium-intracellulare* complex,^{570,753–763} *M. fortuitum*,^{646,648,729,764–766} *M. abscessus*,^{645,767–771} and *M. chelonae* (formerly *M. chelonae*).^{721,722,731,772–779} *Mycobacterium chelonae* and *M. abscessus* can be distinguished from one another using PCR-RFLP (restriction fragment length polymorphism) analysis.⁷⁸⁰ Unlike *M. chelonae/abscessus* infections that occur in immunocompromised hosts, *M. fortuitum* disease most commonly occurs in healthy individuals.^{644,781} Osteomyelitis due to the latter organism has followed a penetrating injury to the foot.⁷⁸² The advent of PCR has allowed *M. avium* to be distinguished from *M. intracellulare*, but few reports have appeared using this new technique for this purpose.⁶⁰⁸ PCR techniques can rapidly detect and speciate many mycobacteria.^{783,784} An increasing number of disseminated infections caused by the *M. avium-intracellulare* complex are being reported in patients with AIDS,

Figure 23.17 *Mycobacterium marinum*. (A) There is marked acanthosis. (B) Granulomas are present in the lower dermis with intervening chronic inflammatory cells. (H&E)

although cutaneous lesions are uncommon in these cases.^{755,785-788} They are sometimes seen after the initiation of highly active antiretroviral therapy (HAART).⁷⁸⁹ The appearance of skin lesions is thought to be a manifestation of partial immune restoration revealing a latent mycobacterial infection.^{790,791} Sporotrichoid lesions are a rare manifestation of infection with *M. avium* complex.⁷⁹² This organism has been reported, limited to the skin, in a patient with systemic lupus erythematosus.⁷⁹³ It has also been isolated from lesional skin in a case of erythema multiforme.⁷⁹⁴ Dissemination of a localized cutaneous

infection can occur if immunosuppressive therapy is commenced mistakenly.⁷⁹⁵

Histopathology³⁸⁶

The changes are not species specific. They include tuberculoid granulomas, sometimes caseous necrosis (*M. gordonae*),⁷⁹⁶ poorly formed granulomas, nonspecific chronic inflammation, suppuration, and intermediate forms.³⁸⁶ Less common patterns include a septal⁷⁹⁷ or mixed lobular and septal panniculitis,³⁸⁶ a necrotizing folliculitis,⁷⁹⁸ a lichenoid and granulomatous dermatitis,⁷⁰¹ and a diffuse histiocytic infiltrate in the dermis resembling lepromatous leprosy⁷⁹⁹ or the cells of Gaucher's disease.⁸⁰⁰ One example of a large subcutaneous nodule due to *M. scrofulaceum* featured a dermal histiocytic infiltrate within a fibrotic stroma; numerous acid-fast bacilli were identified both within histiocytes and in the dermis.⁸⁰¹ The presence of poorly formed granulomas with intervening chronic inflammation and foci of suppuration should always raise the suspicion of an infection by atypical mycobacteria. Suppurative inflammation with microabscess formation and pseudocyst formation with numerous acid-fast bacilli is a characteristic feature of infections caused by rapid-growing species.⁸⁰² The location of the inflammation is inconstant, with no specific relationship to the organism or the type of inflammation.³⁸⁶ The inflammation is mostly centered on the dermis, with some extension into the subcutis; the latter is more likely in immunosuppressed patients.⁷⁹⁸

Infections caused by *M. haemophilum* are posing an increasing diagnostic problem. They may present with non-granulomatous or paucigranulomatous reactions without necrosis. A mixed suppurative and granulomatous reaction is still the most common pattern seen with this organism, but lichenoid (interface) and nonspecific perivascular inflammation as well as necrotizing lymphocytic vasculitis are sometimes reported.⁷⁴¹

In cases with spindle cell pseudotumors, there are plump to spindle-shaped cells with a histiocytic to myofibroblastic appearance.^{712,714,803,804} The stroma contains collagen bundles of variable thickness. Acid-fast bacilli may be quite numerous within the spindle cells and epithelioid histiocytes.⁸⁰⁴ The spindle cells stain for CD68 and sometimes desmin, but not for factor XIIIa.⁸⁰⁵

Organisms are difficult to find, even in preparations stained to demonstrate acid-fast bacilli. They may be plentiful in cases with a histiocytoid pattern and in some infections with *M. avium*, *M. abscessus*, *M. chelonae*, and *M. intracellulare*, although they are rarely as plentiful as in infections with *M. ulcerans*. The bacilli of *M. kansasii* are larger, broader, and more coarsely beaded than other mycobacteria.⁶⁶⁵ Grains formed of bacillary clumps and somewhat resembling those seen in mycetomas have been reported in a case of *M. chelonae* infection.⁷⁷² Intracellular nontuberculous (atypical) mycobacteria have been reported to be PAS positive.⁸⁰⁶ Note that *Vibrio exortquens*, a rare cause of skin ulcers, is weakly acid fast in tissue sections;⁸⁰⁷ granulomas may also be present. Also in this category (skin lesions with granulomas and acid-fast bacilli) are the lesions caused by *Rhodococcus*.⁸⁰⁸

Differential diagnosis

The dermal infiltration by large histiocytes with pale cytoplasm as reported in *M. scrofulaceum* and other atypical mycobacterial infections could resemble dermatofibroma, epithelioid cell histiocytoma, reticulohistiocytoma, Langerhans cell histiocytosis, atypical fibroxanthoma, cellular neurothekeoma, or even Spitz nevus. Differential immunostaining would be of value. The cells of mycobacterial infections would be CD68 positive and lack the other markers associated with these disparate lesions; Ziehl-Neelsen staining is sometimes decisive in these histiocytoid lesions, in that numerous acid-fast organisms can be identified.⁸⁰¹

LEPROSY

Leprosy (lepra) is a chronic infection caused by *Mycobacterium leprae*. It affects mainly the skin, nasal mucosa, and peripheral nerves. Leprosy is most prevalent in tropical countries, particularly India and those in Southeast Asia, Central Africa, and Central and South America, particularly Brazil. In India, which has two-thirds of the global leprosy burden, the case detection rate has remained stubbornly around 5 per 10,000 population.⁸⁰⁹ Of the 122 countries in which leprosy was considered endemic, 107 had achieved the 'elimination target' (1 case per 10,000 population) by the year 2002.⁸¹⁰ Leprosy is uncommon in Europe and the United States, where it occurs in persons from other countries; diagnosis is sometimes delayed.^{811,812} In 2001, there were 6518 active cases of leprosy registered in the United States.⁸¹⁰ There appears to be an endemic focus of leprosy in Texas, around the Gulf Coast.⁸¹³ Leprosy is also rare in Australia, with an average of 8 cases per year during a recent 5-year period.⁸¹⁴ Approximately half of these cases occur in the indigenous population, with most other cases in persons from endemic countries.⁸¹⁴

Mycobacterium leprae is an obligate, intracellular, gram-positive organism that is also acid fast, although less so than *M. tuberculosis*. The organism cannot be grown *in vitro*, although claims of successful cultivation are made from time to time.⁸¹⁵ *Mycobacterium leprae* can be grown in the footpads of mice and in the nine-banded armadillo, an animal in which natural infection also occurs. The sooty mangabey monkey is another host.⁸¹⁶ *Mycobacterium leprae* shares many antigens with other mycobacteria; it also possesses a unique antigen, phenolic glycolipid-1 (PGL-1).^{817,818} Experimental studies are currently attempting to determine the exact role of the various components of the immune system in the defense against this organism.⁸¹⁹ *Mycobacterium leprae* is found predominantly in three main cell types in the skin: Schwann cells, endothelial/perithelial cells, and cells of the monocyte-macrophage system.⁸²⁰

The incubation period of leprosy is not known with certainty, but it is thought to average 5 years.⁸¹⁷ This uncertainty and the long period make any study of the mode of transmission difficult. The organism is of low infectivity, and prolonged and/or close contact with patients who have the disease is considered necessary for transmission to occur.⁸²¹ The incidence of conjugal leprosy is low, which is further testimony to its low infectivity.⁸²² Contact with the armadillo may be an important source of infection in some countries.^{823,824} There may also be a genetic predisposition to the disease.⁸²⁵ The HLA genotypes HLA-DR2 and -DQ1 appear to increase personal susceptibility to leprosy.⁸²⁶ A strong leprosy susceptibility factor has been linked to chromosome 6q25-q26 and a further locus is at 6p21.⁸²⁷ A low-producing lymphotoxin- α allele has been identified as a major risk factor for early onset leprosy.⁸²⁷ Gene variants involved in NOD2 (nucleotide-binding oligomerization domain-containing protein 2)-mediated signaling pathways are believed to be involved with the immunological control of intracellular *M. leprae*.⁸²⁸ The portal of entry of the organism is not known, but the skin and upper respiratory tract, particularly the nasal mucosa, are probable sites.⁸²⁹ Droplet infection is the most likely mode of transmission, although rare cases of inoculation infection have been recorded,^{829,830} particularly from tattooing.⁸³¹

Concurrent infection with *M. tuberculosis* is rare, even in endemic countries.^{832,833}

Clinical classification of leprosy

Leprosy exhibits a spectrum of clinical characteristics that correlate with the histopathological changes and the immunological status of the individual.^{817,820,834-837} At one end of the spectrum is tuberculoid leprosy (TT), which is a highly resistant form with few lesions and a paucity of organisms (paucibacillary leprosy).⁸³⁸ At the other end is lepromatous leprosy (LL), in which there are numerous lesions with myriad

bacilli (multibacillary leprosy) and an associated defective cellular immune response.^{838,839} This response may, in part, result from a genetic alteration in the IL-12 receptor β_2 gene, leading to a reduced production of IFN- γ by Th1 lymphocytes.⁸⁴⁰ In between these poles, there are clinical forms that are classified as borderline-tuberculoid (BT), borderline (BB), and borderline-lepromatous (BL) leprosy. The clinical state of an individual may alter along this scale, although the polar forms (TT and LL) are the most stable and the borderline form (BB) the most labile. This categorization, known as the Ridley-Jopling classification,^{835,841} is often modified by the addition of subpolar forms at either end of the spectrum (TTs and LLs), giving additional categories of subpolar lepromatous leprosy and subpolar tuberculoid leprosy. In the author's view, this is taking 'splitting' to a level that is difficult to justify. There is also an indeterminate form of leprosy, which is classically the first lesion to develop, although it may be overlooked clinically.

Indeterminate leprosy is most often recognized in endemic regions.⁸⁴² It presents as single or multiple slightly hypopigmented or faintly erythematous macules, usually on the limbs.⁸⁴³ Sensation is normal or only slightly impaired. Indeterminate lesions often heal spontaneously, but in approximately 25% of cases this form develops into one of the determinate types, usually in the borderline region of the spectrum.⁸²² The clinical features of the determinate forms are now considered in further detail.

Tuberculoid leprosy (TT) is a relatively stable form and the most common type in India and Africa.⁸²² There are one or several sharply defined reddish-brown anesthetic plaques that are distributed asymmetrically on the trunk or limbs.⁸⁴⁴ An enlarged nerve may be seen entering and leaving the plaque; other superficial nerves, such as the ulnar and popliteal nerves, may also be enlarged, leading to nerve palsy.⁸⁴⁴ Giant nerve 'abscesses' may occur,^{845,846} and a case of pure neural leprosy with ulnar nerve necrosis has been reported.⁸⁴⁷ The lepromin test is positive. This category is often divided into polar and subpolar forms. The T helper (Th) type 1 cytokines, principally IL-2 and IFN- γ , are more strongly expressed in tuberculoid leprosy than in other types.⁸⁴⁸

Borderline-tuberculoid leprosy (BT) is usually associated with more numerous lesions than tuberculoid leprosy, and these are usually smaller. Daughter (satellite) patches may develop. Hypoesthesia and impairment of hair growth within the lesions are often present.⁸²² A trigeminal trophic syndrome has been reported in this form of the disease.⁸⁴⁹ Patients with BT leprosy also have a Th1-type cytokine profile.⁸⁵⁰

Borderline leprosy (BB) is an unstable form with erythematous or copper-colored infiltrated patches that are often annular. Margins are often ill-defined. Large plaques with islands of sparing can have a 'Swiss cheese' appearance.⁸⁵¹ Borderline leprosy typically upgrades (toward the tuberculoid pole) or downgrades (toward the lepromatous pole) along the disease spectrum.⁸⁵¹

Borderline-lepromatous leprosy (BL) is associated with more numerous lesions that are less well defined, more shiny, and less anesthetic than those at the tuberculoid end of the spectrum. Nodular lesions resembling those seen in lepromatous leprosy may be present. A rare subepidermal bullous form has been reported.⁸⁵² Rarely, it may present as a solitary cutaneous plaque.⁸⁵³ Nerve involvement, without cutaneous lesions other than hypoesthesia, has been seen.^{854,855} Skin lesions in these patients have mainly a Th2 cytokine profile.⁸⁵⁰

Lepromatous leprosy (LL) usually develops from borderline or borderline-lepromatous forms by a downgrading reaction. Polar and subpolar forms have been recognized. It is a systemic disease, although the primary clinical manifestations are in the skin.⁸⁵⁶ Mucosal involvement may lead to ulceration of the nasal septum, whereas nerve lesions may result in acral anesthesia, claw hand, and foot drop.⁸²² The cutaneous lesions, which are usually symmetrical, include multiple small macules, infiltrated plaques, and nodules with poorly defined borders.

Multiple facial nodules give a bovine appearance, and this is usually accompanied by sparse eyebrows.⁸²² A segmental arrangement of lesions in a zoster-like distribution has been described.⁸⁵⁷ Various autoantibodies have been demonstrated in this form of leprosy.⁸⁵⁸ This may explain the increased incidence of vitiligo.⁸⁵⁹ Cryoglobulinemia has been reported in up to 95% of cases. It may result in leg ulcers.⁸⁶⁰ Th2 cytokines, notably IL-4, IL-5, and IL-10, are characteristic of this form of leprosy.⁸⁴⁸ The Th1–Th2 dichotomy in leprosy has been challenged recently,⁸⁶¹ and there is a third, Th0 cytokine profile featuring both IFN- γ and IL-4. Th17 cells are associated with this nonpolarized Th0 phenotype and may play a role in patients who do not have Th1 and Th2 polarization.⁸⁶² For example, associated IL-17 isoforms are significantly expressed in healthy contacts and patients with tuberculoïd leprosy.⁸⁶² There is a high expression of COX-2 in LL.⁸⁶³ Experimental attempts are being made to culture, *ex vivo*, macrophages from patients with lepromatous leprosy to understand better the mechanism of this specific anergy in these patients.⁸⁶⁴

In cases of lepromatous leprosy, the diagnosis can be confirmed by PCR amplification of the mycobacterial heat shock 65 gene (*Hsp65*) from DNA extracted from skin lesions.^{865,866}

Histoid leprosy is a rare variant of the nodular variety of lepromatous leprosy and is characterized by the presence of cutaneous and/or subcutaneous nodules and plaques on apparently normal skin.^{867–872} It may be caused by a drug-resistant strain of *M. leprae* because it usually develops in cases of long standing.⁸⁶⁸ It may also develop in untreated lepromatous leprosy.⁸⁷³

Although only a few instances of leprosy have been reported in patients with AIDS, the long incubation period and its occurrence in areas of Central Africa where AIDS is also endemic suggest that leprosy complicating AIDS may be a problem in the future.^{874–877}

Visceral leprosy is more common than would appear from the little attention it has received.⁸⁷⁸ A significant number of patients with internal organ involvement by *M. leprae* are asymptomatic. An excellent review of this topic has been published.⁸⁷⁹

Reactional states in leprosy⁸²²

Reactional states are acute episodes that interrupt the usual chronic course and clinical stability of leprosy.^{880,881} They are expressions of immunological instability. Pregnancy, which causes a relative decrease in cellular immunity, may precipitate a reactional state.⁸⁸² They may also occur as a manifestation of the immune reconstitution inflammatory syndrome seen in patients with HIV treated with HAART.⁸⁸³ The reactions, which are major causes of tissue injury and morbidity, have been subdivided into three variants: the lepra reaction (type I), erythema nodosum leprosum (type II), and Lucio's phenomenon (sometimes included with type II reactions, and at other times designated type III).^{880,884} Not included in these categories, but nevertheless a manifestation of an upgrading reaction, is the rare sporotrichoid pattern caused by spread along peripheral nerves.⁸⁸⁵ RAGE (receptor for advanced glycation end products), a member of the immunoglobulin superfamily, and its ligand EN-RAGE are involved in triggering the release of key inflammatory mediators. They appear to be involved in the proinflammatory process, especially during the lepra reaction.⁸⁸⁶ The expression of B7, on the surface of antigen-presenting cells, precedes reactional episodes in patients with multibacillary leprosy.⁸⁸⁷

Lepra (type I) reactions occur in borderline leprosy and are usually associated with a shift toward the tuberculoïd pole (upgrading) as a result of an increase in delayed hypersensitivity. It is an example of a type IV cell-mediated reaction. Uncommonly, the shift is toward the lepromatous pole (a downgrading reaction).^{881,888} Lepra reactions are often seen in approximately the first 6 months of therapy, but they may occur in untreated patients or be associated with pregnancy, stress, or intercurrent infections.⁸⁸⁹ It may follow the completion of therapy.⁸⁹⁰ They are characterized by edema and increased erythema

of skin lesions, sometimes accompanied by ulceration and the development of new lesions. Constitutional symptoms and neuritis may be present.⁸⁹¹

Erythema nodosum leprosum (type II reaction) occurs in 25–70% of all cases of lepromatous leprosy^{880,892} and occasionally in association with the borderline-lepromatous form.^{893–895} There are crops of painful, erythematous, and violaceous nodules, particularly involving the extremities.⁸⁹⁶ The occurrence of bullous lesions is exceedingly rare.⁸⁹⁷ Individual lesions last 7–20 days.⁸⁹⁸ Severe constitutional symptoms may be present.^{878,898} The pattern varies somewhat in severity in different ethnic groups,⁸⁸⁴ with necrotizing lesions sometimes developing.⁸⁹⁹ Type II reactions are the result of an immune complex-mediated vasculitis,⁸⁹³ although the participation of certain cytokines indicates that some cell-mediated components are involved.⁹⁰⁰

Lucio's phenomenon (erythema necroticans) is seen mainly in Mexicans with the diffuse non-nodular form of lepromatous leprosy.^{898,901,902} It is rare in other ethnic groups.^{903–906} Hemorrhagic ulcers form as a result of the underlying necrotizing vasculitis⁹⁰⁷ or of vascular occlusion due to endothelial swelling and thrombosis.⁹⁰¹ Some cases are fatal.⁹⁰⁴

Multiple drug therapy has been used for many years in the treatment of leprosy to address dapsone resistance, to reduce the length of therapy (resulting in improved compliance), and to keep rifampin (rifampicin) in all therapeutic regimens because of its effectiveness, even when taken once a month.⁸¹⁰ The current WHO recommended treatment is as follows:⁸¹⁰

1. For paucibacillary disease, 600 mg rifampin monthly and 100 mg dapsone daily with six cycles in 9 months
2. For multibacillary disease, 600 mg rifampin and 300 mg clofazimine monthly and 100 mg dapsone and 50 mg clofazimine daily with 24 cycles in 36 months or 12 cycles in 18 months
3. For single paucibacillary lesions (usually indeterminate leprosy), one dose of ROM (rifampin 600 mg, ofloxacin 400 mg, minocycline 100 mg).

Anti-leprosy vaccination can be immunoprophylactic or immunotherapeutic. It is used in high-incidence countries such as India.⁸¹⁰

In type I reactional states, systemic corticosteroids are necessary if neuritis is present. In milder cases, NSAIDs can be used.^{810,889} In type II reactions, corticosteroids are used if neuritis is present. In the absence of neuritis, drugs such as thalidomide, colchicine, and pentoxifylline can be used.⁸¹⁰ Steroids and the addition of an augmented clofazimine dose should be added to the WHO schedule in cases of Lucio's phenomenon.⁹⁰²

Histopathology^{822,841}

Skin biopsies should include the full thickness of the dermis and should be taken from the most active edge of a lesion. The bacilli may be detected in tissue sections using the Fite–Faraco staining method or an immunofluorescent technique.⁹⁰⁸ Immunohistochemical staining of paraffin-embedded tissues can also be carried out using nonspecific identification with BCG antibody or specific identification using a polyclonal anti-*M. leprae* antibody. One study showed no particular advantage to using these techniques over traditional histochemical methods.⁹⁰⁹

Two distinct types of histological changes are found in leprosy: the *lepromatous reaction*, in which large numbers of macrophages in the dermis are parasitized with acid-fast bacilli (Fig. 23.18), and the *tuberculoïd reaction*, in which there are tubercle-like aggregates of epithelioid cells, multinucleate giant cells, and lymphocytes, with bacilli being difficult to find. These histological patterns are seen at either end of the clinical spectrum of leprosy; features overlapping with those of borderline forms may be present. Sometimes there is a disparity between the clinical and the histological subclassification of leprosy.⁹¹⁰ Early lesions are mostly of indeterminate or tuberculoïd type.⁹¹¹

Figure 23.18 Lepromatous leprosy. Numerous acid-fast bacilli are present within macrophages and lying free in the dermis. (Wade-Fite)

Indeterminate leprosy is characterized by a superficial and deep dermal infiltrate around blood vessels, dermal appendages, and nerves, composed predominantly of lymphocytes with a few macrophages (Fig. 23.19).⁸³⁵ Mast cells are markedly increased in number, and they may extend into the small nerves in the deep dermis.⁹¹² Less than 5% of the dermis is involved by the infiltrate.⁹¹² Mild proliferation of Schwann cells may occur, but marked neural thickening is quite uncommon.⁸⁴³ The term neuritic leprosy is used if there is an inflammatory infiltrate in any layer of the nerve fascicle and one or more acid-fast bacilli in the nerve.⁹¹³ There may be a few lymphocytes in the epidermis; this is one of the earliest changes to occur in leprosy.⁹¹¹ Bacilli are usually quite difficult to find,⁹¹¹ but if serial sections are cut and a small dermal nerve is followed, sooner or later a single bacillus or a small group of bacilli will be discovered.⁸⁴² The mechanism of the hypopigmentation in this and other forms of leprosy is still not clear. There is a reduction in melanin in the basal layer; in some reports, a decreased number of melanocytes has also been recorded.⁹¹⁴

Tuberculoid leprosy (polar and subpolar) shows a tuberculoid reaction throughout the dermis, with noncaseating granulomas composed of epithelioid cells, some Langhans giant cells, and lymphocytes (Fig. 23.20).⁸⁴⁴ The predominant lymphocyte present is the T-helper cell, which is found throughout the granuloma, whereas T-suppressor cells predominate in the lymphocyte mantle that surrounds the granulomas.^{915,916} There are said to be fewer lymphocytes in the subpolar form – a rather tenuous feature on which to base a distinct category. Granulomas may erode the undersurface of the epidermis, and they may also extend into peripheral nerves and into the arrectores pilorum.⁸⁴⁴ Lepromatous phlebitis is rarely seen in this form of the disease.⁹¹⁷ Vascular involvement is more common in disseminated disease. The S100 stain is superior to H&E in identifying nerve fragmentation in tuberculoid leprosy.⁹¹⁸ Inflammation often engulfs the sweat glands.⁹¹¹ Bacilli are found in less than 50% of cases.⁸⁴⁴ Perineural granulomas may persist for at least 18 months after the cessation of effective therapy.⁹¹⁹

Borderline-tuberculoid leprosy differs from tuberculoid leprosy in several ways.⁸²² Tubercle formation may be less evident, and nerve destruction is not as complete. A subepidermal grenz zone is invariably present. Lymphocytes and Langhans cells are usually not as plentiful in the granulomas as in tuberculoid leprosy.

In *borderline leprosy*, there are collections of epithelioid cells without the formation of well-defined granulomas. Langhans giant cells are absent, and lymphocytes are more dispersed. Occasional bacilli can be found.

Figure 23.19 (A) Indeterminate leprosy. (B) There is a superficial and deep infiltrate of lymphocytes with periappendageal and perineural extension. Epithelioid cells are present. (H&E)

In *borderline-lepromatous leprosy*, there are small collections of macrophages rather than epithelioid cells. These large cells have abundant granular cytoplasm, although a few may have foamy cytoplasm as seen in lepromatous leprosy.⁸²² A variable number of lymphocytes are present, and some of these are in the vicinity of small dermal nerves. A grenz zone is present in both borderline-lepromatous and true lepromatous leprosy.⁹²⁰

Lepromatous leprosy (polar and subpolar) is characterized by collections and sheets of heavily parasitized macrophages within the dermis, with a sparse sprinkling of lymphocytes, the majority of which are CD8⁺ (Fig. 23.21).⁹¹⁶ Rarely, subcutaneous and deep dermal inflammatory nodules are present.⁹²¹ In older lesions, the macrophages have a foamy appearance (lepra cells, Virchow cells). Numerous acid-fast bacilli are present in macrophages, sweat glands, nerves, Schwann cells, and vascular endothelium⁹²² – a finding that has been confirmed by electron microscopy.⁹²³ An increase in angiogenesis also occurs.⁹²⁴ Marked melanin incontinence is a rare finding.⁹²⁵ The macrophages express S100 protein.⁹²⁶ The organisms in the macrophages may be arranged in parallel array, forming clusters, or in large masses known as globi (Fig. 23.22). There are fewer globi and a few more T lymphocytes in the subpolar form than in the polar form.⁹²⁶ If normal-appearing skin is biopsied in leprosy, more than half of the cases will show histological changes of leprosy. This is more likely at the lepromatous end of the

Figure 23.20 Tuberculoid leprosy. (A) Noncaseating granulomas extend throughout the dermis. (B) A deep cutaneous nerve contains a granuloma. (H&E)

spectrum.⁹²⁷⁻⁹²⁹ A neuritic phase often precedes the development of visible cutaneous lesions.⁹²⁹ Using immunohistochemical staining for BB1 and 2D7, basophils were found in the cutaneous infiltrates of lepromatous leprosy and not in lesions of borderline-lepromatous, borderline-tuberculoid, or tuberculoid leprosy.⁹³⁰ Transepidermal elimination of lepra bacilli has been reported in both conventional lepromatous leprosy and the histoid variant;^{861,931} the former was also associated with pseudoepitheliomatous hyperplasia.⁸⁶¹

Fine needle aspiration cytology is also effective in the diagnosis of lepromatous leprosy; smears from these lesions show numerous foamy macrophages with both intracellular and extracellular 'negative images' that prove to be positive with acid-fast staining.⁹³²

In *histoid leprosy*, the epidermis is frequently atrophic.⁹³³ There are circumscribed nodular lesions consisting predominantly of spindle-shaped cells with some polygonal forms; these are sometimes

separated from the overlying epidermis by a grenz zone, but this occurs in less than half of cases.⁸³³ The cells are arranged in an intertwining pattern.^{867,868} Some cases may resemble a fibrohistiocytic tumor (Fig. 23.23). Epithelioid cells were not identified in one study of 17 cases.⁹³³ Small collections of foamy macrophages may also be present. The component cells contain numerous acid-fast bacilli, which are longer than the usual bacilli of leprosy and are aligned along the long axis of the cell.⁸⁶⁸ The spindle-shaped cells are dermal dendritic cells expressing factor XIIIa.⁹²⁶ CD68⁺ macrophages are also present.⁹³⁴ Keratin 'balls', or 'bullets', containing lepra bacilli and attached to the stratum corneum have been identified in a case of histoid leprosy.⁹³⁵

Lepra (type I) reactions show edema, an increase in lymphocytes and sometimes giant cells, as well as the formation of small clusters of epithelioid cells.^{936,937} Edema also occurs in the epithelioid cell granulomas.⁹³⁸ In severe cases, fibrinoid necrosis may be present, and this is followed by scarring.⁸⁸⁸ This is the picture seen in the usual upgrading reaction. In downgrading reactions, there is replacement of lymphocytes and epithelioid cells by collections of macrophages, and there is a corresponding increase in the number of bacilli.⁸⁸⁸

Erythema nodosum leprosum is characterized by edema of the papillary dermis and a mixed dermal infiltrate of neutrophils and lymphocytes superimposed on collections of macrophages.⁸⁹³ Bullous lesions are sometimes seen.^{897,939} There are relatively more T lymphocytes of helper-inducer type (CD4⁺) than in nonreactive lepromatous leprosy.^{915,940} This appears to be due to an absolute reduction in the number of T-suppressor (CD8⁺) cells,⁹⁴¹ which predominate in lepromatous leprosy.⁹⁴² A vasculitis is often present (Fig. 23.24).^{893,898,942} There may be involvement of the subcutis, with the development of a mixed lobular and septal panniculitis; however, in the majority of cases, involvement of the dermis is the primary and predominant finding.⁸⁹⁹ Macrophages in the dermis contain fragmented organisms.⁹⁴³ Direct immunofluorescence reveals the presence of C3 and IgG in the walls of dermal blood vessels.⁸⁹³

Lucio's phenomenon is usually the result of a necrotizing vasculitis of the small vessels in the upper and mid dermis, with associated infarction of the epidermis.^{898,944} At other times, there is prominent endothelial swelling and thrombosis of superficial vessels without a vasculitis.⁹⁰¹ The endothelial cells and macrophages in the dermis contain numerous bacilli.^{898,903} These organisms have also been found in thrombi and in the lumina of vessels.⁹⁴⁵ There is usually only a mild inflammatory infiltrate, with fewer neutrophils than in erythema nodosum leprosum.⁹⁰³

Differential diagnosis

Indeterminate leprosy lesions show nonspecific changes that can resemble a variety of inflammatory dermatoses. However, the clinical context of the lesions may suggest the diagnosis. Special staining is occasionally helpful, or additional sampling of more infiltrative lesions may produce a higher yield of positive results. Lepromatous lesions must be distinguished from xanthomas. The grenz zone separating large aggregates of foamy macrophages from the epidermis is a typical feature of lepromatous leprosy. The Virchow cells of lepromatous leprosy contain neutral fat and phospholipid and not cholesterol; therefore, the lipid is not doubly refractile when examined with formalin-fixed frozen sections. However, as a practical matter, this would rarely be helpful unless the diagnosis is strongly suspected before obtaining a biopsy. The key to diagnosis is recognizing the organisms, which produce grayish, somewhat filamentous aggregates that can be seen on H&E-stained sections and allow definitive diagnosis with acid-fast staining. Fite stain is recommended for this purpose because lepra bacilli decolorize readily with the usual Ziehl-Neelsen method for acid-fast bacilli. The granulomas of tuberculoid leprosy can be mistaken for those of sarcoidosis. The finding that granulomas surround degenerated nerve elements (aided with S100 staining) is a

Figure 23.23 (A) Histoid leprosy. (B) The cells mimic a fibrohistiocytic tumor; a globus can be identified in the upper right of the figure. (H&E) (C) Numerous acid-fast bacilli can be identified, some of which are aligned along the long axis of the cell. (Fite stain)

Figure 23.24 Erythema nodosum leprosum. In this case, there is a heavy neutrophilic infiltrate with leukocytoclastic vasculitis. (H&E)

helpful clue to the diagnosis. Dr. James H. Graham also suggested using a reticulin stain, in that sarcoidal granulomas contain a delicate reticulin meshwork, whereas this finding is absent in the granulomas of tuberculoid leprosy. Organisms can occasionally be identified in tuberculoid leprosy, but their detection requires careful search, sometimes involving multiple levels or the use of focus-floating microscopy. Ultimately, PCR methodology may be necessary to establish the diagnosis in this type of lesion. Type II lepra reactions (erythema nodosum leprosum and the Lucio phenomenon) must be distinguished from other causes of leukocytoclastic vasculitis or cutaneous thrombosis. This may be a particular problem when vasculitis coexists with lipidization, as occurs in papular neutrophilic xanthoma or later stages of erythema elevatum diutinum. Again, in these circumstances, detection of organisms with special stains is essential.

MISCELLANEOUS BACTERIAL INFECTIONS

Some of the organisms to be considered in this miscellaneous category have received attention recently as possible biological agents of terrorism. Because it is easily disseminated, anthrax tops the list of potential organisms. Others include *tularemia*, the plague (*Yersinia pestis*), brucellosis, and psittacosis.⁹⁴⁶

ANTHRAX

Anthrax is a zoonosis that primarily affects grazing herbivorous animals.⁹⁴⁷ Humans are incidental hosts. It is mainly an occupational disease occurring in those who handle hair, wool, hide, or the carcasses of infected animals.^{948–951} The ritual of smearing cow's blood on the forehead is another mode of transmission of anthrax to children.⁹⁵² The causative organism, *Bacillus anthracis*, may enter the body by the skin or by inhalation or ingestion.⁹⁵³ Anthrax is now an exceedingly rare infection.⁹⁵⁴ It has the potential to be used as an agent of bioterrorism.⁹⁴⁶ Anthrax poses a potential threat for laboratory workers.⁹⁵⁵ It can exist for decades as environmental spores.

The initial cutaneous lesion is usually on an exposed site. It begins as a papule, which soon becomes bullous and then ulcerates, with the formation of a hemorrhagic crust (eschar).⁹⁵⁶ A ring of satellite vesicles may form. Similar lesions have been reported with other *Bacillus*

species, including *B. cereus*, *B. pumilus*, and *B. megaterium*, suggesting that reports of *Bacillus* 'contaminants' in cultures of cutaneous lesions should be regarded with caution.⁹⁵⁷ Extensive lesions have been reported in a diabetic patient.⁹⁵⁸ The pathogenesis of anthrax is related to the production of exotoxins: edema toxin and lethal toxin.⁹⁴⁶ They may result in a necrotizing vasculitis. Hemorrhagic lymphadenopathy, constitutional symptoms, and even a fatal septicemia may accompany the cutaneous lesion.

A swab protocol for laboratory diagnosis, called the 'swab extraction tube system', has demonstrated good recovery of viable *B. anthracis* in culture and consistent detection of its DNA by real-time PCR.⁹⁵⁹ Vaccines are available, and treatment/prophylaxis with antibiotics is effective when started early.⁹⁴⁶ Penicillin used to be the drug of choice,⁹⁶⁰ but β -lactamase-producing strains of organism have been encountered. Ciprofloxacin and amoxicillin have been used to treat anthrax.⁹⁶¹ Doxycycline and one or two additional antimicrobials have also been recommended.⁹⁶²

Histopathology^{948,949,963}

There is necrosis of the epidermis and upper dermis, with surrounding edema, fibrin extravasation, and hemorrhage. The blood vessels are conspicuously dilated. Fibrin thrombi are sometimes present. Inflammatory cells are often surprisingly sparse, although sometimes a florid cellulitis is present with focal abscess formation.⁹⁴⁹ Spongiosis and vesiculation may occur in the epidermis adjacent to the ulceration.

Bacillus anthracis can be seen, usually in large numbers, in the exudate. It is easily recognized by its large size, square-cut ends, and a tendency to be in chains. It is gram positive. If antibiotic therapy has been given, organisms are sparse and often do not stain positively by the Gram procedure.

Differential diagnosis

The combination of necrosis, ulceration, and pronounced dermal edema with neutrophils certainly suggests other infectious diseases, including necrotizing fasciitis, although in the latter example the clinical findings are quite different. Other non-infectious dermatoses may be considered, particularly those that feature combinations of dermal edema and neutrophilic infiltration, such as pyoderma gangrenosum and Sweet's syndrome. Pronounced dermal edema occurs in the two closely related viral diseases, orf and milker's nodules. In those infections, there are marked elongation of the rete ridges and vacuolated keratinocytes with intranuclear eosinophilic inclusion bodies. However, in the acute weeping stage of those lesions, the epidermis is necrotic and inclusions are not identifiable so that there may be greater overlap with the findings in anthrax. The key to the diagnosis of anthrax is a high index of suspicion and Gram staining, which is likely to show the characteristic organisms. The infection can be confirmed by culture studies. However, there are several potential caveats. First, with age, *B. anthracis* organisms can show variable staining or become gram negative. Second, if laboratories are not alerted to the possibility of anthrax, it is possible that cultures indicating the presence of *Bacillus* species may not be further analyzed due to the likelihood of common contaminant organisms, such as *B. cereus*. However, as mentioned previously, these 'contaminants' are also capable of producing cutaneous lesions similar to those that occur in anthrax.

BRUCELLOSIS

Brucellosis is a re-emerging disease in some countries. It is transmitted primarily from farm animals to humans.⁶³⁵ Cutaneous involvement occurs in 5–10% of patients with brucellosis.⁹⁶⁴ It takes the form of a disseminated papulonodular eruption or an urticarial maculopapular rash.^{964–966} Occasionally, erythema nodosum-like nodules develop.^{635,966} Skin lesions may not develop for many weeks after the onset of

symptoms of brucellosis.⁹⁶⁴ A dermatitis has also been reported on the forearms of veterinarians involved in the manual removal of placentas from aborting cows infected with *Brucella abortus*.⁹⁶⁵

Histopathology^{964,965}

The maculopapular lesions usually have a nonspecific appearance with a mild perivascular infiltrate of lymphocytes in the upper dermis;⁹⁶⁵ leukocytoclastic vasculitis was described in a recent case.⁹⁶⁷ The papulonodules have an infiltrate of lymphocytes and histiocytes, which is both perivascular and periadnexal. There is also focal granulomatous change; multinucleate giant cells are uncommon. Granulomatous vasculitis has also been described.⁹⁶⁷ Focal exocytosis of inflammatory cells and keratinocyte necrosis may be present. A leukocytoclastic vasculitis is exceedingly rare.⁹⁶⁸

The erythema nodosum-like lesions show a septal panniculitis, with considerable extension of the infiltrate into the fat lobules accompanied by focal necrosis. Plasma cells are also abundant. These features are not usually associated with lesions of typical erythema nodosum. A lobular panniculitis with vasculitis has also been reported.⁶³⁵

The treatment of brucellosis is variable. Oral doxycycline and intramuscular streptomycin were successful in one report.⁶³⁵

YERSINIOSIS

Yersiniosis is a generally accepted term for diseases caused by *Yersinia pseudotuberculosis* and *Y. enterocolitica*. The incidence of cutaneous manifestations in yersiniosis is not known, although in some countries the disease is responsible for 10% or more of cases of erythema nodosum.^{969,970} Erythema multiforme and figurate and nonspecific erythemas may also occur.^{969,971}

Histopathology

As in brucellosis, the erythema nodosum-like lesions may show some extension of the infiltrate into the fat lobules, as well as a necrotizing vasculitis and some necrosis.⁹⁶⁹ The appearances in some cases are more in keeping with erythema induratum–nodular vasculitis than with erythema nodosum.

GRANULOMA INGUINALE

Granuloma inguinale (granuloma venereum, donovanosis) is a sexually transmitted disease caused by a small gram-negative bacillus, *Klebsiella granulomatis*. The organism was previously designated *Calymmatobacterium granulomatis*,⁹⁷² but gene sequencing has demonstrated strong identity with species of *Klebsiella* that are human pathogens.⁹⁷³ It has a relatively low level of infectivity. Clinically, the external genitalia are involved in most cases,^{974,975} but occasionally anal, vaginal, oral, or extragenital cutaneous involvement is found.^{976,977} The disease begins after an incubation period of 2–4 weeks. The initial manifestation is a papule, which soon ulcerates. The lesion slowly spreads and may cause extensive destruction of the penis or vulva.^{978–981} It may also spread to involve the adjacent parts of the thighs or lower abdomen.⁹⁷⁶ An association with HIV infection has been recorded.⁹⁸¹ Squamous cell carcinoma may supervene, but care should be taken not to misinterpret the marginal pseudoepitheliomatous hyperplasia as carcinomatous.⁹⁷⁶

The diagnosis is easily made by examination of tissue smears stained by the Wright or Giemsa methods. Smears will show large mononuclear cells containing a number of the organisms, which appear as red-stained intracytoplasmic encapsulated ovoid structures with prominent polar granules. The organism can be cultured in an egg-yolk medium and also by inoculation of the yolk sac of chick embryos. PCR-based tests are available for specific diagnosis.⁹⁷⁷ One of these is

called genital ulcer disease multiplex PCR, with amplification products detected by an enzyme-linked amplicon hybridization assay.⁹⁸²

The quinolone antibiotics have been used to treat the disease, but other antibiotic categories can be used.⁹⁷⁷

Histopathology^{976,983}

The center of the lesion is usually ulcerated, and at the margins there is often well-marked pseudoepitheliomatous hyperplasia. Plasma cells and macrophages predominate in the base of the ulcer, and there are often scattered neutrophil microabscesses as well. Blood vessels are prominent in the ulcer base, and sometimes endothelial swelling is present.⁹⁸³ Transepithelial elimination of macrophages with cytoplasmic organisms has been reported through areas of pseudoepitheliomatous hyperplasia.⁹⁸⁴ The diagnosis is made by finding parasitized macrophages. These are large cells, measuring 20 µm in diameter. Organisms are seldom numerous, but they can be recognized – if with some difficulty – in H&E sections. They are more readily found in silver preparations, such as the Warthin–Starry method (Fig. 23.25), or when stained with Giemsa's solution. Plastic-embedded semithin sections enhance diagnosis.⁹⁸⁵ In these sections, and in smears, the vacuolated nature of the cytoplasm of the parasitized macrophages can be appreciated. The organisms (Donovan bodies) are present singly or in

Figure 23.25 Granuloma inguinale. (A) The infiltrate consists of neutrophils, plasma cells, and parasitized macrophages. (H&E) (B) The organisms can be seen in the cytoplasm of macrophages in this silver preparation. (Warthin–Starry)

Figure 23.26 Imprint from a vulval lesion of granuloma inguinale. Numerous organisms are present in vacuoles in the cytoplasm of a macrophage. (Giemsa)

clusters in the vacuoles (Fig. 23.26). They measure 1–2 μm in diameter and show bipolar staining in silver preparations. For this reason, they have been likened to minute safety pins. There may be up to several dozen in a macrophage.

Electron microscopy

The organism may be seen within phagosomes of macrophages.⁹⁸⁶ On semithin sections obtained from Epon-embedded specimens, the organisms appear to be surrounded by a vacuolated structure that represents a phagolysosome.⁹⁸⁷ However, ultrastructural study has also shown a layer of homogeneous material surrounding the organisms, suggesting that there may be a ‘true’ surrounding capsule.⁹⁸⁸

Differential diagnosis

The microscopic morphology of the granulomatous lesions, in the appropriate clinical context, is suggestive of granuloma inguinale but not entirely diagnostic because many of the changes can be seen in ulcerative diseases due to a variety of causes. Therefore, diagnosis depends on finding the organisms. Their intracellular location raises consideration of the other major ‘parasitized histiocyte’ diseases: rhinoscleroma, histoplasmosis, and leishmaniasis. The ability to distinguish among these is enhanced to a great extent by knowledge of the clinical presentation. However, the organisms of granuloma inguinale are slightly smaller (~1 or 2 μm) than those in the other three conditions, whose organisms are all in the 2- to 4- μm range. The organisms of rhinoscleroma (also representing a species of *Klebsiella*) lack a surrounding capsule-like space. Histoplasma organisms are surrounded by a clear space that does not represent a true capsule, and they stain well with the traditional methods for fungi: PAS and Grocott’s methenamine silver stain (GMS). *Leishmania* are nonencapsulated organisms that feature both a nucleus and a kinetoplast, best demonstrated with a Giemsa stain. *Toxoplasma* organisms can sometimes be found in macrophages but may be organized as pseudocysts and are also present in keratinocytes of epidermis and sweat ducts and within arrector pili muscle. These organisms are weakly positive for PAS but are negative for the GMS stain. They can also be stained with antibodies specific for *Toxoplasma*.

CHANCROID

Chancroid is a sexually transmitted disease (STD) caused by the gram-negative bacillus *Haemophilus ducreyi*.^{989–993} It has a short incubation

Figure 23.27 Chancroid. Three horizontal zones can be identified, although they are not sharply delineated: a superficial zone of fibrin and neutrophils, a zone of proliferative vessels, and a deeper zone composed of lymphocytes and plasma cells. (H&E)

period and presents as painful, irregular, non-indurated single or multiple ulcers, usually in the genital area or perineum.^{994–996} Sometimes the ulcers are on the lower legs.⁹⁹⁷ Clinically, the ulcers may sometimes be difficult to distinguish from granuloma inguinale or even herpes simplex.^{996,998} Approximately half of the patients have tender inguinal lymphadenopathy, and occasionally draining sinuses arise from the suppurating nodes.

Chancroid is now seen less frequently than previously in Western countries, usually occurring as limited but significant outbreaks.^{999–1002} The main reservoir for disease transmission is prostitutes.¹⁰⁰³ However, it is a major cause of genital ulceration in Africa, where it appears to facilitate the heterosexual spread of HIV.^{1004,1005} It has been estimated that the probability of transmitting chancroid from an infected to an uninfected person during a single sexual exposure is 0.35.¹⁰⁰⁶ Gram-negative rods forming parallel chains (‘school of fish’ appearance) may be seen in smears. Selective agars are also available that facilitate the rapid isolation of *H. ducreyi*.^{1007,1008}

Treatment with erythromycin or ciprofloxacin can be used to treat chancroid. In some countries, broad-spectrum antibiotics are used to treat concurrent STDs. Intramuscular benzathine penicillin is sometimes curative.⁹⁹⁷ Azithromycin and ceftriaxone can also be used.¹⁰⁰⁶

Histopathology^{989,1001}

There is usually a broad area of ulceration, in the base of which three zones can be discerned. Superficially, there is tissue necrosis, fibrin, red cells, and neutrophils. Beneath this is a zone of vascular proliferation, with prominent endothelial cells and a mixed inflammatory infiltrate. In the deepest zone, the infiltrate is more chronic, with plasma cells and lymphocytes predominating (Fig. 23.27). The epidermis

adjacent to the ulcer shows acanthosis, some overlying parakeratosis, and occasional intraepidermal microabscesses.

A Giemsa stain or a silver impregnation method shows organisms both singly and in short chains, lying free and within histiocytes in the base of the ulcer.

Differential diagnosis

Despite the previous description of the characteristic configuration of a chancroid lesion, this arrangement may not be clearly observable in all cases, and in any event the characteristic 'zones' may not be very sharply delineated. This may be due in part to biopsy technique; however, ulcerated lesions due to a number of different causes tend to show fibrin, proliferative vessels, and admixed acute and chronic inflammation, making specific diagnosis difficult, particularly when organisms are so difficult to identify in tissue sections. Two STDs that bear a clinical resemblance to (and may even coexist with) chancroid are herpesvirus infection and syphilis. Therefore, histopathologic evaluation should also include a careful search for viroplasmic changes or immunohistochemical evaluation for herpes simplex or treponemal antigens. Ulcerative diseases that are non-infectious, such as aphthosis or Behçet's disease, also show similar morphologic features in biopsy specimens.

RHINOSCLEROMA

Rhinoscleroma is a chronic inflammatory disease of the nasal and oral mucosa caused by the gram-negative bacillus *Klebsiella rhinoscleromatis*.¹⁰⁰⁹ All *Klebsiella pneumoniae* subsp. *rhinoscleromatis* isolates have the capsular serotype K3 and belong to a single clone with single nucleotide polymorphisms.¹⁰¹⁰ In advanced cases, it may spread to involve the larynx, trachea, bronchi, and lips.¹⁰¹¹ Rhinoscleroma is endemic in areas of Africa, Asia, and Latin America. It is spread by direct or indirect contact. The incubation period is long.¹⁰⁰⁹ Rhinoscleroma is an opportunistic infection that can occur in patients infected with HIV.¹⁰¹²

Initially, there is a nonspecific rhinitis with the development of a purulent nasal discharge and some hypertrophy of the inflamed mucous membrane.¹⁰⁰⁹ This is followed by an infiltrative and nodular stage, during which the involved tissues become swollen and eventually deformed.¹⁰¹¹ Obstruction of the nasal cavity can be caused by the friable inflammatory masses. There is scarring and further deformity in the late stages. That is, there are three stages of development: rhinitic, infiltrative, and cicatricial stages.¹⁰¹¹

It is rare for spontaneous cure to occur, and accordingly, prolonged treatment with antibiotics is required.¹⁰¹³ The tetracyclines, fluoroquinolones, gentamicin, and trimethoprim-sulfamethoxazole have all been used at different times.^{1013,1014}

Histopathology

In the fully developed lesions of rhinoscleroma, the changes are diagnostic, with a variable admixture of plasma cells with conspicuous Russell bodies, and large mononuclear cells with vacuolated cytoplasm (Mikulicz cells) (Fig. 23.28). In addition, there are some lymphocytes and foci of neutrophils. Lymphocyte populations in cutaneous lesions include both CD4⁺ and CD8⁺ T cells (helper T cells predominating), but there are also large numbers of non-plasmacellular CD20⁺ B cells.¹⁰¹⁵ The Mikulicz cell, which varies from 10 to 100 µm in diameter, is a macrophage.¹⁰¹⁶ Mikulicz cells are often dispersed rather than grouped in discrete aggregates.¹⁰¹⁷ The causative organisms may be seen in the cytoplasm of these cells in PAS and Gram preparations. However, they are best visualized with silver impregnation methods, particularly the Warthin-Starry stain (Fig. 23.29).¹⁰¹⁸ The organisms are easily cultured. The unique characteristics of this infectious agent have made

possible the development of a specific PCR assay, allowing for a rapid and accurate confirmatory molecular diagnosis of rhinoscleroma.¹⁰¹⁰

The dense inflammatory infiltrate may cause ulceration or atrophy of the overlying mucosa. Sometimes the mucosa is hyperplastic, even to the extent of pseudoepitheliomatous hyperplasia.¹⁰¹⁸

Fine needle aspiration cytology shows numerous foamy macrophages (Mikulicz cells) with small, central to eccentric nuclei and indistinct nuclei, in a background of lymphocytes and plasma cells; occasional gram-negative bacilli can be identified within macrophages.¹⁰¹⁹

Electron microscopy

The vacuolated Mikulicz cells are macrophages with phagosomes containing bacterial mucopolysaccharide as well as some bacteria.¹⁰¹⁶ There is often fragmentation of the limiting membrane of some of the phagosomes.¹⁰¹⁶ Plasma cells are sometimes vacuolated to a limited extent. Russell bodies are readily seen in the plasma cells and extracellularly.

Differential diagnosis

Differentiation from other infectious diseases with 'parasitized histiocytes' was discussed previously (see *Granuloma inguinale*), with particular reference to the morphology of these microorganisms in tissues. In rhinoscleroma, the vacuolated Mikulicz cells are particularly distinctive, much more so than is the case in granuloma inguinale, which in turn is said to have dermal neutrophilic microabscesses as one of its distinctive features. Pseudo-Mikulicz cells have recently been reported adjacent to a superficially invasive squamous cell carcinoma; no organisms were found in this case, and progressive disease was not documented.¹⁰²⁰ Cells similar to Mikulicz cells can also be seen in leprosy and in nonspecific reactions to toxins produced by a variety of pathogens.¹⁰²¹ In lepromatous leprosy, there are large aggregates of foamy macrophages (Virchow cells) containing both lipid and aggregates of acid-fast lepra bacilli. In situations in which the macrophagic cells have more eosinophilic cytoplasm, granular cell tumor should be considered, and S100 staining may be helpful. In malakoplakia, characteristic macrophages (von Hansemann cells) frequently contain targetoid calcific bodies, known as Michaelis-Gutmann bodies (see later). Small groupings of Mikulicz cells may resemble the clear cells of metastatic renal cell carcinoma, but those tumor cells stain positively for low-molecular-weight cytokeratins and RCC-MA, and they lack CD68 expression. Plasma cells can be encountered in any of these disorders and in addition can be numerous in other situations; examples include secondary syphilis (in which they are arranged around vessels in a 'coat-sleeved' configuration), plasmacytoma, and as a host response to malignant epithelial tumors such as basal cell carcinoma and squamous cell carcinoma. Russell bodies are occasionally prominent in plasma cell infiltrates due to a variety of causes, but among the 'parasitized histiocyte' diseases, they are most characteristic of rhinoscleroma. In the editor's experience, they are often difficult to identify in neoplastic plasmacellular proliferations such as plasmacytoma or cutaneous involvement in multiple myeloma.

Of particular current interest is the sometimes close microscopic resemblance between rhinoscleroma and cutaneous Rosai-Dorfman disease. Both are characterized by distinctive macrophages and infiltrates that contain lymphocytes and numerous plasma cells. Elevated antibody titers to *Klebsiella* species were described in a case of Rosai-Dorfman disease as early as 1976,¹⁰²² and co-existence of the two conditions (but involving separate sites) is known to have occurred. In recent years, there have been examples of Rosai-Dorfman disease misdiagnosed as rhinoscleroma¹⁰²³ and of rhinoscleroma mimicking Rosai-Dorfman disease, complete with macrophages demonstrating emperipolesis.¹⁰²⁴ In the latter series, the macrophages engaged in emperipolesis were S100 negative and CD68 positive. Even more intriguing is a recent report of rhinoscleroma apparently coexisting with Rosai-Dorfman disease in the same lesion; microscopic features

Figure 23.28 (A) Rhinoscleroma. (B) The inflammatory infiltrate consists of an admixture of plasma cells and vacuolated macrophages (Mikulicz cells). (H&E)

Figure 23.29 Rhinoscleroma. The organisms can be seen on this silver stain. (Warthin–Starry)

of both conditions were present, including S100⁺ macrophages containing gram-negative bacilli but also demonstrating emperipolesis.¹⁰²⁵ It appears that bacterial stains and cultures, and S100 immunostaining, can most often be used to differentiate between these two conditions, but there remains the intriguing possibility that at least some cases of Rosai–Dorfman disease may be triggered by *Klebsiella* species or possibly by other infectious agents.

TULAREMIA

Tularemia is named after Tulare County, California, where its occurrence was first recognized.¹⁰²⁶ It is caused by *Francisella tularensis*, a minute gram-negative coccobacillus that produces a fatal insect-borne septicemic infection in ground squirrels and other rodents. The disease is transmitted to humans either by the bite of an infected vector, such as mosquitoes or ticks,¹⁰²⁷ or by contact with an infected rodent or rabbit.^{1026,1027} It has been recognized in areas of the United States,^{1028,1029} Canada,¹⁰³⁰ and Russia, and rarely in the British Isles and other areas of Europe. Skin lesions occur only in the ulceroglandular form of the disease.¹⁰³¹ This is characterized by a papule at the site of the initial

inoculation, followed by an ascending lymphangitis. Nodules develop along the course of the affected lymphatics, as in the lymphangitic type of sporotrichosis.¹⁰²⁶ The occurrence of erythema nodosum and erythema multiforme has been described.¹⁰³² Severe constitutional symptoms are usual.¹⁰³³

Streptomycin is the drug of choice, but other aminoglycosides can also be used, as can tetracyclines, chloramphenicol, third-generation cephalosporins, rifampin (rifampicin), and erythromycin.¹⁰³⁴ A human live vaccine has been developed; it is currently undergoing investigations.¹⁰³⁵

Histopathology

The primary lesion is an ulcer, with necrosis involving the epidermis and upper dermis. The adjacent epidermis is usually acanthotic with some spongiosis (Fig. 23.30). In acute lesions, there is focal necrosis and suppuration, whereas in more chronic lesions a granulomatous picture has been described around the necrotic focus in the dermis. Affected lymph nodes show central zones of necrosis containing neutrophils, surrounded by palisaded granulomatous inflammation and an outer layer of lymphocytes.¹⁰³⁶ This structure is sometimes termed a 'stellate abscess', although a star shape is not always clearly identified.

The causative organism cannot be seen in conventional histological preparations. It can be demonstrated in histological sections and in

films of exudate by direct immunofluorescence, following treatment with fluorescein-labeled specific antiserum.¹⁰²⁸ *Francisella tularensis* is a hazard to laboratory workers.¹⁰²⁹

LISTERIOSIS

Listeriosis is a rare infection of neonates, elderly patients, and immunosuppressed patients, including those with HIV infection. It may also involve pregnant women. Cutaneous infections most often occur in veterinarians and others who work directly with animal products of conception, but they also occur with exposure to soil and vegetation.¹⁰³⁷

The organism, *Listeria monocytogenes*, is a gram-positive coccobacillus that can replicate in macrophages. Bacteremia, with or without meningitis, is the usual clinical presentation.¹⁰³⁸ Cutaneous lesions may be papular, pustular, or purpuric.

Histopathology

The epidermis shows mild spongiosis with lymphocyte exocytosis.¹⁰³⁸ In pustular lesions, subcorneal and intraepidermal neutrophils are present. The dermis contains a mixed inflammatory cell infiltrate with many macrophages. Gram-positive coccobacilli are present in macrophages, in adnexal structures, and lying free in the dermis or in epidermal inflammatory cells.

CAT-SCRATCH DISEASE

Cat-scratch disease is a self-limited illness characterized by the development, at the site of a scratch by a cat, of a papule or crusted nodule, which is followed approximately 2 weeks later by regional lymphadenitis.^{1039–1042} In 1 or 2% of patients, severe systemic illness may develop: this may include an oculoglandular syndrome, pleurisy, encephalitis, osteomyelitis,¹⁰⁴³ and splenomegaly.¹⁰⁴⁴ Other cutaneous manifestations have included a plaque-like eruption,¹⁰⁴⁵ erythema nodosum, urticaria, erythema marginatum, a Sweet's syndrome-like eruption,¹⁰⁴⁶ and purpura.^{1042,1047}

Small gram-negative bacilli have been demonstrated in the skin^{1039,1044} and lymph nodes^{1033,1044,1047–1050} of most cases, using the Warthin–Starry silver stain or the Brown–Hopps modification of the Gram stain. The organism has been classified as *Bartonella henselae*. It is possible that the related bacillus *Afipia felis* may also be responsible (as originally reported), but there is a growing consensus that *B. henselae* is the predominant pathogen. *Bartonella clarridgeiae* has been isolated from several cases.¹⁰⁴⁵

The bacillus responsible for cat-scratch disease (*B. henselae*) has an etiological role in the causation of bacillary angiomatosis (epithelioid angiomatosis), a rare vascular proliferation seen in patients with AIDS (see p. 1098).^{1051,1052} Another eruptive vascular tumor, verruga peruana (see p. 1099), is produced by another strain of *Bartonella* – *B. bacilliformis*.

Another species of *Bartonella* (*B. quintana*) is the agent of trench fever, a disease transmitted from human to human by the body louse. There is a high prevalence of this infection in homeless persons.¹⁰⁵³

Although the lesions of verruga peruana usually resolve without antibiotics, these drugs are often used for the other *Bartonella* infections, particularly in immunosuppressed individuals. The quinolones and oral erythromycin are used in these circumstances. Azithromycin hastens resolution of adenopathy in cat-scratch disease.¹⁰⁵⁴

Histopathology^{1039,1055}

The epidermal changes are variable and include acanthosis and ulceration. There is usually a zone of necrosis in the upper dermis, and this is surrounded by a mantle of macrophages and lymphocytes (Fig. 23.31). Neutrophils and eosinophils are often present around zones of

Figure 23.30 Tularemia. This is a biopsy of a chronic lesion. There is a scale-crust composed of necrotic cellular debris, representing the remnants of an ulcer. The adjacent epidermis is acanthotic with a degree of spongiosis. Papillary dermal edema and a predominantly lymphocytic infiltrate are present in the dermis; granulomatous elements are not observed in this particular example. (H&E)

Figure 23.31 Cat-scratch disease. There is a central zone of necrosis and a surrounding mantle of macrophages, lymphocytes, and some granulomas. (H&E)

Figure 23.32 Cat-scratch disease. With a silver method, organisms can be seen in an inflammatory focus. (Warthin–Starry)

necrosis. Multinucleate cells and well-defined granulomas may be present. Lymph node biopsies show similar but often better developed findings, including the characteristic ‘stellate’ abscess, consisting of a central zone of necrosis containing numerous neutrophils, surrounded by palisades of macrophages, which in turn are surrounded by a zone of lymphocytes.¹⁰⁵⁵ Organisms are seen within macrophages and lying free, particularly in areas of necrosis and suppuration.¹⁰⁴⁴ They can be found with tissue Gram stains such as Brown and Brenn, but they are better demonstrated with silver methods such as the Warthin–Starry stain (Fig. 23.32). They can also be identified in lymph nodes or skin biopsy specimens by immunohistochemical staining using a commercially available monoclonal antibody for *B. henselae*.^{1056,1057} A rapid PCR-based detection of the causative organism can be carried out on fresh or paraffin-embedded samples.¹⁰⁵⁸

Differential diagnosis

Findings in skin lesions of cat-scratch disease are characteristic but not pathognomonic, and the changes could be mimicked by other condi-

tions that feature palisaded necrobiotic granulomas, including tuberculosis, granuloma annulare, lupus miliaris, and the short-lived primary cutaneous lesions of lymphogranuloma venereum. The ‘stellate abscess’ found in lymph nodes is also typical for this disease but can be found in a number of other conditions, including tularemia, lymphogranuloma venereum, and sporotrichosis. The editor has also seen similar abscesses within lymph nodes draining the site of vaccination therapy for the treatment of melanoma. Therefore, detection of organisms using silver stains or PCR methodology is the key to making a specific diagnosis.

MALAKOPLAKIA

Malakoplakia is a rare chronic inflammatory disease that occurs predominantly in the urogenital tract, especially the bladder. Fewer than 50 cases involving the skin and subcutaneous tissue have been reported.^{1059–1063} Nearly half of these patients were immunosuppressed;¹⁰⁶⁴ occasionally, this was due to AIDS.^{1065,1066} Cutaneous involvement is usually in the vulva¹⁰⁶⁷ and perianal region,^{1068,1069} where yellow-pink indurated or polypoid masses have been described. Less common sites are the axilla,¹⁰⁷⁰ forehead,¹⁰⁷¹ scalp,¹⁰⁷² an injection site,¹⁰⁷³ eyelid, neck, hands, wrists, thighs, and buttocks.¹⁰⁷⁴

Although the pathogenesis of malakoplakia is uncertain, it appears to result from an acquired defect in the intracellular destruction of phagocytosed bacteria, usually *Escherichia coli*.¹⁰⁷⁵ In the skin, *Staph. aureus* has also been isolated.¹⁰⁷⁶

No deaths have been directly associated with cutaneous malakoplakia.¹⁰⁷² Treatment consists of a combination of surgery and antibiotic therapy. The highest cure rate is associated with the use of quinolones and trimethoprim–sulfamethoxazole.¹⁰⁷² In the setting of organ transplantation, discontinuance or tapering of immunosuppressant therapy can also be considered.¹⁰⁷²

Histopathology¹⁰⁵⁹

Malakoplakia is a chronic inflammatory process characterized by sheets of closely packed macrophages (von Hanseman cells). These cells contain PAS-positive, diastase-resistant, and (sometimes) iron-positive inclusions, a variable proportion of which appear as calcospherites with a homogeneous or target-like appearance – the Michaelis–Gutmann bodies. These stain with the von Kossa method (Fig. 23.33).¹⁰⁷⁶ There is also a scattering of lymphocytes and plasma cells. Immunostaining with polyclonal anti-*M. bovis* antibodies, a method for detecting bacterial organisms in low concentration, has been successful in demonstrating bacteria in malakoplakia.¹⁰⁷¹

Diagnosis can be made by fine needle aspiration cytology, which demonstrates macrophages containing the characteristic Michaelis–Gutmann bodies in a background inflammatory infiltrate that includes lymphocytes, neutrophils, eosinophils, and plasma cells.¹⁰⁷⁷

Differential diagnosis

Macrophages with granular cytoplasm could bear some resemblance to the cells of granular cell tumor. The cells of granular cell tumor are polyhedral, have small central hyperchromatic nuclei, and occasionally contain large granules termed pustule-ovoid bodies of Milian. The classic examples of this tumor are thought to be composed of modified Schwann cells and are S100 positive, a result not seen in malakoplakia. Granular cell changes in other tumors (e.g., dermatofibroma and basal cell carcinoma) have other configurational features more in keeping with ordinary examples of those tumors, as well as characteristic immunohistochemical findings. The rare examples of the primitive non-neural granular cell tumor are negative for S100 but stain for other markers such as NK1/C3 and PGP9.5.¹⁰⁷⁸ At low magnification, the granularity of von Hanseman cells can suggest xanthoma, but close

Figure 23.33 Malakoplakia. (A) Large, granular macrophages (von Hansemann cells) are present within the dermis. (H&E) (B) PAS-positive inclusions are identified. (PAS) (C) Calcified spherules are present within the cytoplasm of these macrophages. (von Kossa)

inspection of cell detail shows that the cytoplasm of these cells is granular rather than finely vacuolated. Sometimes, changes in healing wounds include accumulations of macrophages with granular cytoplasm. However, in none of these potentially confounding lesions are there structures with the morphologic and staining characteristics of Michaelis–Gutmann bodies. Infectious diseases that could resemble

malakoplakia include tuberculosis, Whipple’s disease (a rare event in skin),¹⁰⁷⁹ lepromatous leprosy, cryptococcosis, and leishmaniasis. Special stains for microorganisms and tissue culture are necessary. Other reactive and neoplastic processes that could potentially be diagnostically problematic include foreign body granuloma, sarcoidosis, hemophagocytic syndromes, Langerhans cell histiocytosis, and lymphoma.

‘SAGO PALM’ DISEASE

‘Sago palm’ disease, also known as Sepik granuloma, is a rare condition that appears to be restricted to the Sepik district of New Guinea.¹⁰⁸⁰ It appears to follow injury by the sago palm (*Metroxylon*), but additional types of injury may also allow the entry of the causative organism, a gram-positive bacillus. Affected individuals usually present with multiple cutaneous nodules on the extremities, but the face can also be involved. The organism has never been cultured.

Histopathology

There is a diffuse dermal infiltrate by large foamy histiocytes admixed with some plasma cells, lymphocytes, and fibroblasts. A syncytium of amorphous pink material extends between the histiocytes. It is PAS positive. The material contains numerous gray, round to oval dots, representing gram-positive organisms surrounded by ground substance.

CHLAMYDIAL INFECTIONS

Chlamydiae are obligate intracellular organisms that share many features with bacteria, including a discrete cell wall. There are two morphologically distinct species, *Chlamydia trachomatis* and *C. psittaci*. The latter is responsible for psittacosis, a pneumonia derived from infected birds, whereas different serotypes of *C. trachomatis* are responsible for trachoma, urethritis, and lymphogranuloma venereum. The diagnosis can be confirmed by culture of the organism or by serology.

PSITTACOSIS

Psittacosis, caused by *C. psittaci*, usually presents as a pneumonic illness with various constitutional symptoms. Some patients develop a morbilliform rash or lesions resembling the rose spots of typhoid fever. Erythema nodosum,¹⁰⁸¹ erythema multiforme, erythema marginatum,¹⁰⁸² and disseminated intravascular coagulation¹⁰⁸³ with cutaneous manifestations have also been reported. The findings are not specific for psittacosis, either clinically or histopathologically.

LYMPHOGRANULOMA VENEREUM

Lymphogranuloma venereum (LGV), or lymphogranuloma inguinale, is a sexually transmitted disease caused by certain serovars/serotypes (L1, L2, and L3) of *C. trachomatis*.^{991,992} Worldwide in distribution,¹⁰⁸⁴ it is most frequent in areas of Asia, Africa, and South America. Recent outbreaks, involving mainly the L2 strain, have occurred in areas of Europe and in the United States.¹⁰⁸⁵ Most of these cases occurred in men having sex with men.¹⁰⁸⁵ Clinically, three stages are recognized.¹⁰⁸⁶ The initial lesion, which follows a few days or weeks after exposure to the organism, consists of a small papule, ulcer, or herpetiform vesicle on the penis, labia, or vaginal wall. Extragenital sites of involvement have been recorded.¹⁰⁸⁷ The primary lesion is transient and often imperceptible. The secondary stage, which follows several weeks after the initial exposure, consists of regional lymphadenopathy. If the

inguinal nodes are involved, enlarging buboes develop with draining sinuses. There may be constitutional symptoms at this stage. Erythema multiforme and erythema nodosum rarely develop. The tertiary stage, which is more common in women, encompasses the sequelae of the earlier inflammatory stages.¹⁰⁸⁸ There may be rectal strictures, fistula formation, and rarely genital elephantiasis related to lymphedema.^{1089,1090} The duration of the disease may be prolonged in HIV-positive patients.⁹⁹²

The organism can be isolated in a tissue culture system or in the yolk sac of eggs.¹⁰⁸⁶ Serological methods are most commonly used to establish a diagnosis. They do not distinguish between the different serotypes of *C. trachomatis*. A microimmunofluorescence test can detect antichlamydial antibodies to a range of serological variants of *C. trachomatis*.¹⁰⁸⁶ Various PCR-based tests have been developed in the past few years. DNA sequencing of the variable segments of the *omp1* gene (outer membrane protein gene) is used to type the serovars/serotypes.¹⁰⁸⁵

Oral doxycycline is the treatment of choice.¹⁰⁸⁵ Tetracycline is another alternative, but the daily dose must be 2 g. Oral sulfadiazine and erythromycin have also been used.^{1034,1085}

Histopathology

The primary lesion is not commonly biopsied. Ulceration is usually present, with a dense underlying infiltrate of plasma cells and lymphocytes.¹⁰⁹¹ There is thickening of vessel walls and some endothelial swelling. Small sinus tracts may lead to the surface. A few epithelioid cell collections may be present.¹⁰⁹¹

The characteristic lesions occur in the lymph nodes in the second stage, with the development of stellate abscesses with a poorly formed palisade of epithelioid cells and histiocytes. Sinus formation also occurs. In later lesions, there is variable fibrosis.

Direct immunofluorescence, using a fluorescein-labeled antibody to *C. trachomatis*, has been used to confirm the diagnosis.¹⁰⁹²

RICKETTSIAL INFECTIONS

Rickettsiae are small obligate intracellular bacteria that are transmitted in most instances by the bite of an arthropod. The various species of *Rickettsia* are endemic in different geographical locations, and this has influenced the naming of some of the infections.^{1093–1095} Table 23.2 lists the various rickettsial infections of humans, the corresponding etiological species, and the mode of transmission. The organism for scrub typhus has been reclassified from the genus *Rickettsia* to *Orientia*.¹⁰⁹⁶

Table 23.2 Rickettsial infections

Disease	Organism	Mode of transmission
Rocky Mountain spotted fever	<i>R. rickettsii</i>	Tick
Boutonneuse fever	<i>R. conorii</i>	Tick
African tick bite fever	<i>R. africae</i>	Tick
Rickettsialpox	<i>R. akari</i>	Mite
Siberian tick typhus	<i>R. sibirica</i>	Tick
Queensland tick typhus	<i>R. australis</i>	Tick
Epidemic typhus	<i>R. prowazakii</i>	Louse feces
Murine typhus	<i>R. mooseri (typhi)</i>	Flea feces
Scrub typhus	<i>O. tsutsugamushi</i>	Mite
Q fever	<i>Coxiella burnetii</i>	Aerosol

Rickettsiae usually produce an acute febrile illness accompanied by headache, myalgia, malaise, and morbidity. Rocky Mountain spotted fever has a mortality of approximately 5%.^{64,1097–1100} Its rash begins on the extremities and travels proximally to involve the trunk.¹¹⁰¹ In the United States, children 5–9 years old have the highest incidence.¹¹⁰¹ A specific diagnosis is usually made by serological methods because the attempted isolation of rickettsiae in the laboratory is potentially highly hazardous for the laboratory staff.¹¹⁰² Human granulocytic anaplasmosis (formerly human granulocytic ehrlichiosis), caused by the tick-borne rickettsia-like organism *Anaplasma phagocytophilum*, has some clinical similarities to Rocky Mountain spotted fever.¹¹⁰³ Having a similar vector, anaplasmosis is usually found in the United States in areas where Lyme disease is prevalent.¹¹⁰⁴ It has also been associated with Sweet's syndrome.¹¹⁰⁵

Cutaneous lesions are present in most rickettsial infections, with the exception of Q fever. They are uncommon in African tick bite fever.^{1095,1106} This disease is now being seen in international travelers.^{1107,1108} Usually, there is a macular or maculopapular rash; in rickettsialpox, the rash may be papulovesicular.^{1109,1110} Rickettsialpox is endemic in New York City.¹¹¹¹ A more characteristic lesion is the eschar (tache noire), a crusted ulcer 1 cm or more in diameter that develops at the site of the arthropod bite.¹¹¹² It is thought to result not from the bite but from the inoculation of rickettsiae, which invade vascular endothelial cells.¹¹¹³ The eschar in rickettsialpox needs to be distinguished from anthrax.¹¹¹¹ Eschars are characteristic of rickettsialpox,^{1109,1114} scrub typhus,^{1115,1116} boutonneuse fever,^{1117,1118} Queensland tick typhus,¹¹¹⁹ and Siberian tick typhus.^{1112,1117} An eschar is not found in epidemic typhus or in murine typhus, and it is only rarely found in Rocky Mountain spotted fever.^{1093,1112,1117} Rickettsialpox has been reported in a patient with HIV infection.¹¹²⁰

Rickettsiae proliferate on the endothelium of small blood vessels, releasing cytokines that damage endothelial integrity. This leads to a cascade of events that may terminate in focal occlusive endangiitis.¹¹²¹

Tetracyclines are the treatment of choice.¹¹²⁰ Doxycycline is the tetracycline most often used.

Histopathology

The pathological basis for the cutaneous lesions of rickettsial infections is a lymphocytic vasculitis. The eschars result from coagulative necrosis of the epidermis and underlying dermis.^{1122,1123} A crust overlies this region. Bordering the area of necrosis is a lymphocytic vasculitis, with some fibrinoid necrosis of vessels and related dermal hemorrhage.¹¹¹⁷ Arterioles, and not postcapillary venules, are often involved.¹¹¹⁷ Thrombosis of vessels is sometimes present.¹¹¹⁷ There are often a few neutrophils in the inflammatory infiltrate. Numerous organisms can be demonstrated in vascular endothelium and vessel walls using fluorescein-labeled antisera to the appropriate rickettsial species.

The maculopapular lesions of Rocky Mountain spotted fever show a focal lymphocytic vasculitis with patchy fibrinoid necrosis of small vessels and extravasation of erythrocytes (Fig. 23.34).^{1124,1125} Progression to a leukocytoclastic vasculitis is common.^{1126,1127} The most notable epidermal change is basal vacuolar degeneration with exocytosis of inflammatory cells.¹¹²⁶ *Rickettsia rickettsii* can be demonstrated in endothelium and vascular walls using fluorescein-labeled antisera¹¹²⁸ (Fig. 23.35) or with immunoperoxidase techniques using routine sections.¹¹²⁶

The papulovesicular lesions of rickettsialpox show subepidermal edema associated with exocytosis of mononuclear cells into the epidermis.¹¹⁰⁹ These tend to obscure the dermoepidermal interface. There is a dense perivascular infiltrate in the underlying dermis, with prominence of the endothelial cells of the blood vessels and changes indicative of a mild vasculitis.¹¹⁰⁹ Fibrin thrombi are sometimes present, and there may be extravasation of red cells. The causative organism, *R.*

Figure 23.34 Rocky Mountain spotted fever. There is a lymphocytic vasculitis in the dermis, with erythrocyte extravasation. (H&E)

akari, has not been identified in tissue sections other than by immunofluorescent techniques.^{1109,1114}

The diagnosis of scrub typhus can be confirmed by the immunohistochemical staining of *Orientia tsutsugamushi* in cutaneous lesions. Staining of eschars gives an excellent result.¹⁰⁹⁶

Differential diagnosis

The microscopic differential diagnosis for Rocky Mountain spotted fever includes other forms of lymphocytic vasculitis. Examples are pityriasis lichenoides, pigmented purpuric eruptions, and perniosis. The clinical presentations of these conditions are quite different from Rocky Mountain spotted fever, and other associated microscopic findings are different as well. The latter include substantial epidermal changes in pityriasis lichenoides (although Rocky Mountain spotted

Figure 23.35 Rocky Mountain spotted fever. This is a direct immunofluorescence image obtained from a section of brain from an autopsy case. Green-staining bodies within endothelial cells (arrows) represent *Rickettsia* organisms. (Direct immunofluorescence with anti-rickettsial antibody)

fever, like pityriasis lichenoides, can show vacuolar alteration of the epidermal basilar layer), inflammation confined to superficial dermal vessels in forms of pigmented purpura, and 'fluffy edema' around vessel walls in perniosis. Of greater difficulty are biopsies of later stages of leukocytoclastic vasculitis due to other causes, in which perivascular lymphocytes become more prominent. Correlation with the clinical presentation should point to Rocky Mountain spotted fever as a better diagnostic choice, and that impression could be supported by serologic studies and immunostaining if available.

Primary syphilis	674	Pinta	678	<i>Borrelia</i> -associated B-cell lymphoma	682
Secondary syphilis	674				

INTRODUCTION

The order Spirochaetales has two genera of medical importance, *Treponema* and *Borrelia*. Spirochetes are one of the few bacterial groups for which classic morphological criteria and RNA sequence analyses agree in predicting the phylogenetic relationships among the various members of the order.

TREPONEMATOSES

The treponematoses are caused by infection with the spirochete *Treponema pallidum* and its various subspecies. They include the following:

- Syphilis
- Endemic syphilis (bejel)
- Yaws
- Pinta.

The treponemes responsible for these different diseases are currently indistinguishable on morphological and routine serological grounds, although different names have been given to the various subspecies responsible for each condition; the various subspecies may differ by as little as a single nucleotide. This finding suggests that these organisms have evolved from a common ancestor. The organism cannot be cultivated and maintained on artificial media.¹

Syphilis is usually acquired by sexual (venereal) transmission, whereas the other conditions are contagious and endemic to various countries.

The clinical features of the treponematoses can usually be divided into distinct stages, reflecting initial local infection with the organism, followed by dissemination and the subsequent host response. Serology is usually used to confirm the diagnosis of a treponemal infection.²

Other species of *Treponema* are found in humans: some species are found in the mouth and may be responsible for periodontal disease; others may be found in the sebaceous secretions of the genital region. There is no known clinical significance of these genital treponemes.

The pathogenic mechanisms that give the treponeme its virulence are poorly understood. The organism possesses no secretory apparatus that would deliver virulence factors into the host tissues.³ One possible mechanism is its ability to stimulate human fibroblasts to increase the synthesis of matrix metalloproteinase-1 (MMP-1), which is capable of degrading the surrounding connective tissue.³ Furthermore, the presence of acid repeat proteins (arp) in the genome make it highly immunogenic. They may play a part in the pathogenesis of the disease; they are also potential vaccine candidates.¹

SYPHILIS

Syphilis is an infectious disease of worldwide distribution; it is caused by the spirochete *T. pallidum*.⁴⁻⁷ Its genome was sequenced in 1998.⁸ Although its incidence decreased in the 1980s as a consequence of safer sexual practices resulting from the emergence of the HIV epidemic, since the mid-1990s it has once again emerged as a clinical problem, particularly in men who have sex with other men.⁹⁻¹² The mode of infection is almost always by sexual contact and, consequently, seropositivity for HIV is sometimes present in individuals with active syphilis.¹³⁻¹⁶ Nonsexual transmission (syphilis brephotropica) occurs, rarely, in children from infected parents.¹⁷ Congenital infection is also quite rare, although its incidence appears to be increasing.¹⁸⁻²² Acquired syphilis may be considered in four stages: primary, secondary, latent, and tertiary.²³ Congenital syphilis is considered before the acquired forms.

Congenital syphilis

Congenital syphilis, which usually results from the transplacental infection of the fetus from an infected mother, has been divided into *early*, in which clinical manifestations are seen in the first 2 years of life but mostly in the first 3 months, and *late* forms.²⁴ Prematurity, low birthweight, rhinorrhea, and mucocutaneous lesions are typical clinical findings of the *early* form. The nephrotic syndrome is uncommon.²⁵ The skin lesions are varied and include a macular rash, vesiculobullous or scaling lesions, predominantly on the palms and soles,^{26,27} and condylomata lata. Erythema multiforme and diffuse alopecia have also been reported.^{28,29} In a premature newborn with congenital syphilis and pustular and bullous lesions, biopsy of a pustular lesion showed an intraepidermal pustule containing neutrophils and eosinophils.³⁰ Diagnosis is best made by immunoblotting for *T. pallidum*-specific IgM; it is highly sensitive in identifying infants with congenital syphilis.³¹

The significant findings of *late* congenital syphilis include interstitial keratitis, neurosyphilis, as well as bone and cardiovascular disease.³² Classic findings include (1) Higoumanakis' sign – unilateral enlargement of the sternoclavicular portion of the clavicle³³ – and (2) Hutchinson's triad – interstitial keratitis, eighth nerve deafness, and Hutchinson's (notched) incisors.³⁴ Ootosyphilis occurs in both the congenital and the acquired forms of the disease.³⁵

Primary syphilis

The initial lesion of syphilis – the primary chancre – is an indurated painless ulcer with a sharply defined edge that often is surrounded by an inflammatory zone. It is usually found on genital or perianal skin, although approximately 5% of chancres are extragenital.³⁶⁻⁴⁰ The nipple is one such site.⁴¹ The chancre appears approximately 21 days after sexual exposure. In patients with HIV infection, multiple or more extensive chancres are sometimes present.¹⁵ The serous exudate from the ulcer generally contains numerous treponemes, which can be identified by dark-ground microscopy.

In time, the ulcer heals, leaving a small stellate or nondescript scar. The chancre is often accompanied by painless enlargement of the regional lymph nodes.

Histopathology

The epidermis at the periphery of the chancre shows marked acanthosis, but at the center it becomes thin and is eventually lost. The base of the ulcer is infiltrated with lymphocytes and plasma cells, particularly adjacent to the blood vessels, in which there is prominent endothelial swelling. The treponemes can usually be demonstrated by appropriate silver impregnation techniques, such as the Levaditi or Warthin–Starry stains. The May–Grünwald–Giemsa technique can also be used to demonstrate organisms.⁴² Polymerase chain reaction (PCR)-based methods may be used on paraffin-embedded skin biopsy specimens to confirm the presence of the organism.⁴³ On darkfield examination of a smear from a chancre, the *T. pallidum* can be seen as a thin, delicate spiral organism 4–15 µm in length and 0.25 µm in diameter. Electron microscopy has shown *T. pallidum* to be principally in the intercellular spaces in the vicinity of small blood vessels, as well as in macrophages, endothelial cells, and even plasma cells.⁴⁴ Collagen fibers appear to be damaged by the treponeme.⁴⁵ Other means of diagnosis include direct fluorescence or immunohistochemical staining of tissues for *T. pallidum*⁴⁶ or the *in vitro* nucleic acid amplification test for quantitative detection of *T. pallidum* DNA.⁴⁷

Secondary syphilis

In untreated cases, the multiplication of the widely dispersed treponemes results in secondary syphilis approximately 4–8 weeks after the chancre. In addition to the mucocutaneous lesions, there may

be constitutional symptoms, which include fever, lymphadenitis, and hepatitis.^{48,49} A self-limited febrile reaction (the Jarisch–Herxheimer reaction), accompanied by systemic symptoms, may occur following the commencement of antibiotic therapy for syphilis.⁵⁰ Coexistence of a primary chancre with the eruption of secondary syphilis also occurs.⁵¹

The cutaneous lesions of secondary syphilis⁵² are usually maculopapular or erythematous, somewhat psoriasiform lesions; however, lichenoid,⁵³ nodular,^{54–58} corymbous,⁵⁹ annular,⁶⁰ annular verrucous,⁶¹ bullous,^{62,63} follicular,⁶⁴ pustular, rupial, and ulcerative^{65–69} lesions may develop. Secondary syphilis has presented as scrotal eczema.⁷⁰ Atypical clinical presentations, including seronegativity,^{71,72} may occur in patients with coexisting HIV infection.^{15,73–76} Furthermore, an accelerated progression through the various stages of syphilis can occur in these patients. The term ‘lues maligna’ has been applied to the nodulo-ulcerative and necrotic lesions that can occur when there is concurrent HIV infection,^{77–79} although HIV infection is not invariably present.⁸⁰ The lesions of secondary syphilis may mimic a wide variety of skin diseases. Pruritus is only occasionally present.⁸¹ Large, fleshy, somewhat verrucous papules (condylomata lata) may develop in the anogenital region and/or intertriginous areas;⁸² these should not be confused with viral condylomata acuminata (see p. 737). A moth-eaten alopecia (alopecia syphilitica) is a characteristic manifestation of secondary syphilis,^{83–85} whereas diffuse alopecia can be seen as a rare presentation.⁸⁶

Isolated oral lesions are rare in secondary syphilis; they are typically painful and multiple.⁸⁷ A patient with a lesion on the tongue resembling oral hairy leukoplakia has been reported.⁸⁸ Generalized anetoderma has occurred following intravenous penicillin therapy for secondary syphilis in an HIV⁺ patient.⁸⁹

Histopathology

There is considerable variation in the histological pattern.^{49,90–92} Plasma cells may be absent or sparse in up to one-third of all biopsies, and the vascular changes may not be prominent. The infiltrate usually involves both the superficial and the deep dermis, except in the macular lesions, where it is more superficial (Fig. 24.1). Perineural plasma cells are relatively common.⁹³ Eosinophils can be present in lesions of secondary syphilis and are occasionally numerous.⁹⁴ Extension of the inflammatory infiltrate into the subcutis is uncommon.⁴⁹ The infiltrate is predominantly lymphocytic, with some histiocytes and variable numbers of plasma cells (Fig. 24.2). The histiocytic cells express both CD4 and CD14, whereas the majority of lymphocytes are CD8⁺.⁹⁵ Plasma cells are less numerous in macular lesions.⁹⁶ Angiogenesis is common.⁹⁷ Early lesions often show a neutrophilic vascular reaction, which is presumed to be related to immune complex deposition.⁹⁸ A heavy neutrophil infiltrate resembling that in Sweet’s syndrome has been reported.⁹⁹ Follicles and sweat glands may be sleeved by inflammatory cells.⁹⁰ In alopecia syphilitica, a lymphoid infiltrate around hair follicles and follicular keratotic plugging are almost invariable.^{83,84} Peribulbar lymphoid aggregates may be present.⁸³ Immunohistochemical studies have shown the presence of *T. pallidum* limited to the peribulbar region and penetrating into the follicle matrix.¹⁰⁰ Sometimes the dermal infiltrate in secondary syphilis is dense and diffuse, and it has been likened to cutaneous lymphoma,^{101,102} although its heterogeneous nature is against lymphoma. Approximately 5–10% of the cells may be CD30⁺.¹⁰³ A granulomatous pattern may also be seen in secondary syphilis,¹⁰⁴ particularly after approximately 16 weeks of the disease.⁹⁰ Epithelioid granulomas may be found in late secondary syphilis (Fig. 24.3), and there is a report of a palisading granuloma similar to that seen in granuloma annulare.¹⁰⁵ An interstitial infiltrate resembling that of interstitial granuloma annulare has also been reported.¹⁰⁶ Perineural granulomas simulating leprosy may be present.¹⁰⁷ Sarcoidal granulomas are rare.⁵⁶ The epidermis is frequently involved. It may show acanthosis with spongiosis, psoriasiform hyperplasia, and spongiform pustulation,

Figure 24.1 (A) Secondary syphilis. (B) There is a superficial and deep perivascular infiltrate in the dermis. (H&E)

with considerable exocytosis of neutrophils (Fig. 24.4).⁹¹ A lichenoid tissue reaction may be present, particularly in late lesions (Fig. 24.5).¹⁰⁸ In the rare *ulcerative* form, there is necrosis of the upper dermis,⁶⁷ whereas in the *follicular* type there is microabscess formation in the outer root sheath of the hair follicle, or a follicular pustule (Fig. 24.6).

Figure 24.6 Secondary syphilis. A follicular pustule of secondary syphilis. (H&E)

Figure 24.7 Secondary syphilis. With immunohistochemistry, numerous organisms are found beneath the epidermis. (Spirochete immunostain)

There may be perifollicular granulomas⁶⁴ or a mixed acute and granulomatous perifollicular infiltrate including a few plasma cells.¹⁰⁹ Condylomata lata have marked epidermal hyperplasia and a dermal infiltrate that is similar to that seen in other lesions of secondary syphilis. *Treponema pallidum* may be identified in tissue sections using silver stains such as the Warthin–Starry stain or by immunoperoxidase techniques.¹¹⁰ The latter are more sensitive than silver stains,¹¹¹ with a sensitivity of 71% in one study compared to 41% for the silver stain.⁹³ Organisms are found in the dermis more often than in the epidermis using immunohistochemistry (Fig. 24.7).⁹³ The molecular detection of *T. pallidum*, using PCR-based techniques, is likely to become the ‘gold standard’.^{43,112}

Subepidermal vesicles have been reported, uncommonly, as a manifestation of the Jarisch–Herxheimer reaction.⁵⁰ The bullae reported in a case of bullous secondary syphilis were also subepidermal.⁶²

Differential diagnosis

The various manifestations of secondary syphilis can be confused with other disorders showing patchy perivascular dermal infiltrates, especially those with ‘coat-sleeved’ infiltrates around vessels, most notably erythema annulare centrifugum. Plasma cells in the perivascular infiltrates argue for secondary syphilis, which may be further supported by clinical features, special stains (including immunohistochemical methods), and serologic studies. At times, syphilitic lesions can resemble psoriasis, lichen planus, or pityriasis lichenoides, interstitial granuloma annulare, forms of suppurative and/or granulomatous folliculitis, or alopecia areata – the latter showing both diminished anagen follicles and perifollicular infiltrates.⁸⁶ Suggestive evidence of secondary syphilis is provided by the degree of exocytosis of mononucleated cells in lesions with epidermal involvement (more prominent than in psoriasis or lichen planus), the composition of the inflammatory infiltrates (plasma cells are more common in secondary syphilis than in the diseases they resemble), and the degree of vasculopathic change. Finding spirochetes on special staining is obviously definitive. However, it must be realized that they cannot always be found in lesions of secondary syphilis, particularly with silver stains; a negative result does not exclude the diagnosis of syphilis. In addition, plasma cells are not invariably present, or can be sparse, in secondary syphilis lesions. For that reason, serologic studies are advised, and the possibility of a false-negative rapid plasma reagin due to a prozone phenomenon (secondary to antigen excess) must also be kept in mind. Silver stains also detect

melanin, and positively stained melanocytic dendrites should not be confused with intraepidermal spirochetes (staining of melanin within dendrites is beaded in type and lacks the spiral configuration of *T. pallidum*).

Electron microscopy

Electron microscopy has shown only a modest number of treponemes; their outlines are less distinct than those found in primary chancres. The periplastic membrane (the outer envelope) is rarely intact.^{113,114}

Latent syphilis

Even without treatment, the manifestations of secondary syphilis subside spontaneously. During this phase, there are no signs or symptoms, although there is a tendency for cutaneous lesions to relapse in the first few years after the disappearance of the lesions of secondary syphilis. Serology is usually positive, but screening tests may be negative in patients with HIV infection.¹¹⁵ Syphilis incognito is a variant of latent syphilis in which there has been no clinical evidence of a preceding primary or secondary stage.¹¹⁶ Bone lesions, such as osteomyelitis, may be the only apparent clinical manifestation of late latent syphilis.¹¹⁷

Tertiary syphilis

The manifestations of tertiary syphilis appear many years after the initial infection, reflecting the generalized nature of the disease. They involve predominantly the cardiovascular system, the central nervous system, and the skeleton, but lesions also occur in the testes, lymph nodes, and skin.

There are two types of cutaneous lesion in tertiary syphilis: one is nodular and the other a chronic gummatous ulcer.^{118,119} They are usually solitary.¹²⁰ The nodular form presents an undulating advancing border of red-brown scaly nodules, some of which may become ulcerated.¹²¹ Lesions may mimic granuloma annulare.¹²² Tertiary syphilis has presented as an indurated, annular lesion of the scalp with numerous crusted or ulcerated papules in the annular border.¹²³ The gummatous form starts as a deep, firm swelling that eventually breaks down to form an ulcer.

Histopathology

The gummas of tertiary syphilis have large areas of gummatous necrosis with a peripheral inflammatory cell infiltrate that includes lymphocytes, macrophages, giant cells, fibroblasts, and plasma cells (Fig. 24.8). The giant cells are often of Langhans type. There is usually prominent endothelial swelling and sometimes proliferation involving small vessels. One case involving the scalp also showed a lymphoplasmacellular folliculitis with vacuolar alteration of outer root sheath epithelium and numerous apoptotic cells.¹²³ Attempts to demonstrate *T. pallidum* by silver staining techniques are usually unrewarding, although indirect immunofluorescence and PCR-based assays have been used with success.^{112,124} The nodular or tuberculoid lesions show hyperkeratosis, often overlying an atrophic epidermis. There is a superficial and deep mixed inflammatory cell infiltrate, which usually includes plasma cells and tuberculoid granulomas.¹²⁵ Plasma cells may be sparse in an occasional case.¹²⁶ A combination of PCR and focus-floating microscopy using a polyclonal antibody to *T. pallidum* has been recommended for histopathologic diagnosis of late secondary–tertiary syphilis, and it may even be helpful in cases in which serologic testing has failed.¹²⁷

ENDEMIC SYPHILIS (BEJEL)

Brief mention is made of endemic syphilis (nonvenereal syphilis, bejel), a contagious disease found in areas of the Middle East,

Figure 24.8 Tertiary syphilis; chronic gummatous ulcer. An area of gummatous necrosis is surrounded by a chronic and granulomatous dermal infiltrate. (H&E)

particularly the Euphrates Valley.^{128–130} It is caused by an organism *T. pallidum* subsp. *endemicum* closely related to *T. pallidum*; accordingly, serological tests for syphilis are positive.¹³¹ The disease has virtually been eradicated following public health measures initiated by the World Health Organization (WHO). Primary, secondary, and tertiary stages have been described.¹³¹ A primary lesion is rarely detected because of its small size and location within the oral and nasopharyngeal mucosa, but otherwise the clinical and pathological manifestations resemble those of yaws in many respects (discussed next). The main features are ‘mucous patches’ in the mouth and pharynx, as well as cutaneous and bone lesions. An example of endemic syphilis was identified in Canada in a family of immigrants from Senegal – an example of the potential presentation of endemic syphilis in unexpected geographic locations.¹³²

YAWS

Yaws, or frambesia, is a tropical nonvenereal infection caused by *T. pallidum* subsp. *pertenue* (*T. pertenue*), an organism that has hitherto been indistinguishable from *T. pallidum*.^{133–136} Hybridization studies suggest that the subspecies *pertenue* differs from the subspecies *pallidum* by a single nucleotide.¹²⁹ However, no serological test will differentiate yaws from syphilis, although slightly different lesions are produced when the respective organisms are inoculated into hamsters or rabbits.¹³⁶ The distinction is largely clinical, with some assistance from the histopathology. Yaws is contracted usually in childhood and spreads by direct contact, perhaps aided by an insect vector.¹³⁴ Despite successful eradication after World War II, yaws is now returning in some tropical countries.^{133,136–139} It is seen in Central and West Africa, Indonesia, Papua New Guinea, and the Pacific Islands, particularly Vanuatu.^{132,140} An eradication program in India appears to have been successful.¹⁴¹ Reports of treatment failures using penicillin have been reported,¹⁴² but it remains the treatment of choice for yaws.

The *primary* papule, usually on the legs or buttocks, begins 2–4 weeks after inoculation. It develops into a chronic ulcerating papillomatous mass that may persist for months.¹²⁹ The *secondary* stage is characterized by similar, widespread exuberant lesions covered with a discharge. In warm moist areas, such as mucocutaneous junction areas, large condylomatous lesions may develop.¹³³ Hyperkeratotic plaques form on the palms and soles (‘crab yaws’). Periods of exacerbation and

quiescence occur over the next few years, followed by a longer latent phase, which precedes the development of the *tertiary* phase. It consists of chronic gummatous ulcers that occur on the central face or over long bones, often with involvement of the underlying bones. Hyperkeratosis and fissuring of the soles and palms frequently recur.¹³¹ Apart from the bone lesions, there is no systemic involvement. Oral azithromycin has been shown to be as effective as intramuscular penicillin in the treatment of this disease. WHO has begun an initiative to eradicate yaws by 2020.^{143,144} Molecular methods for differentiation among the subspecies of pathogenic *T. pallidum* are being developed.¹⁴⁴

Histopathology

The appearances of the primary and secondary lesions are similar. There is usually prominent epidermal hyperplasia, which is usually of pseudoepitheliomatous rather than psoriasiform type, with overlying scale crust and superficial epidermal edema (Fig. 24.9). There are intraepidermal abscesses and a heavy superficial and mid-dermal infiltrate of plasma cells, lymphocytes, macrophages, neutrophils, and often a few eosinophils. The neutrophils are more prominent superficially. Blood vessels show minimal endothelial swelling. The ulcerative lesions resemble those of syphilis.

The spirochete of yaws, like that of pinta, is most often demonstrated by silver techniques in the epidermis, in contrast to that of syphilis, which is found in the upper dermis (Fig. 24.10).

PINTA

Pinta (carate) is a contagious nonvenereal treponematoses caused by *T. pallidum* subsp. *carateum* (*T. carateum*), which is morphologically identical to *T. pallidum*. Direct skin-to-skin contact is the method of transmission. The disease occurs in the Caribbean area, Central America, and areas of tropical South America.^{129,130,145,146} It appears to be declining in incidence. It affects mainly children and young adults.¹⁴⁰ The lesions of pinta are confined to the skin and become very extensive. There is often overlap between the three clinical stages. Initial lesions are erythematous maculopapules, which grow by peripheral extension and often coalesce. The secondary lesions are widespread, long-lasting scaly plaques that show a striking variety of colors – red, pink, slate blue, and purple. These lesions merge with the late stage, in which depigmentation resembling vitiligo occurs, and sometimes epidermal atrophy.

The treatment of choice is benzathine penicillin G. Alternative therapies, as in other treponematoses, are tetracycline or erythromycin.¹⁴⁰

Histopathology¹⁴⁷

Primary and secondary lesions are identical and show hyperkeratosis, parakeratosis, and acanthosis. There is exocytosis of inflammatory cells, sometimes with intraepidermal abscesses. Hypochromic areas show loss of basal pigmentation with numerous melanophages in the upper dermis. The dermal infiltrate, like the other changes, is heavier in established than in early lesions, and it includes lymphocytes, plasma cells, and sometimes neutrophils. The infiltrate is predominantly superficial and perivascular. The treponemes can be demonstrated by silver methods: they are present mainly in the upper epidermis and are seldom, if ever, found in the dermis.

BORRELIOSES

The borrelioses are an important group of spirochetal infections, found particularly in the temperate zones of Europe, North America, and

Figure 24.9 Yaws. (A) Note the epidermal hyperplasia and edema of the superficial epidermis. (B) There are many plasma cells in the infiltrate. (H&E)

Asia. More than 100,000 cases have been recorded from the United States alone.¹⁴⁸ Unlike the treponematoses, which have no known animal reservoir, the borrelioses are an arthropod-borne infection, usually involving ticks of the genus *Ixodes*. Three genospecies of *Borrelia burgdorferi* have been identified as human pathogens: *B. burgdorferi sensu stricto*, *B. garinii*, and *B. afzelii*. The genetic diversity of

Figure 24.10 Yaws. Numerous fine spirochetes are present. (Warthin–Starry $\times 1500$)

this species complex is considerable, with more than 100 different strains identified in the United States and more than 300 worldwide.¹⁴⁹ Although not known for certain, it is possible that different strains may be associated with different clinical manifestations.¹⁴⁹ *Borrelia burgdorferi* is the only pathogenic genospecies in North America, explaining the rarity in that region of acrodermatitis chronica atrophicans, for which *B. afzelii* is the predominant but not exclusive etiologic agent.¹⁵⁰

The borrelioses are not endemic in Australia. Occasional cases of Lyme disease are seen in travelers returning to Australia, particularly from Europe. Australia does not have the species of ticks responsible for the transmission of *B. burgdorferi* in other countries. Rarely, patients who have never left Australia present with clinical features suggestive of an atypical borreliosis. The author has been shown two such cases in which spirochetes appeared to be present in tissue sections of a skin biopsy from such patients. Serology for *Borrelia* was negative using international criteria. It has been suggested that an as yet undiscovered spirochete may be responsible for these Australian cases. If such an organism exists, the disease it produces shares few of the epidemiological or clinical characteristics of Lyme disease as seen in Europe and the United States.¹⁵¹

Borrelia are involved in the following conditions:

- Erythema migrans
- Acrodermatitis chronica atrophicans
- *Borrelia*-associated lymphocytoma cutis
- *Borrelia*-associated B-cell lymphoma.

It has been suggested that progressive facial hemiatrophy (Parry–Romberg disease) may be a borreliosis, but this suggestion has not yet been confirmed by others.¹⁵²

Borrelia burgdorferi has also been identified in several of the diseases of collagen, including eosinophilic fasciitis (borrelial fasciitis),¹⁵³ morphea, lichen sclerosus et atrophicus, and atrophoderma of Pasini and Pierini.¹⁵⁴ These conditions appear to have other etiologies as well; accordingly, they are discussed in Chapter 11, pages 348–364. Using focus floating microscopy, a sensitive technique for detecting *Borrelia* species in tissue sections (see later), spirochetal microorganisms have been detected in cases of necrobiotic xanthogranuloma.^{155,156} Orofacial granulomatosis and the Melkersson–Rosenthal syndrome do not appear to be caused by *Borrelia*.^{157,158}

Although most borrelioses result from arthropod-borne infections, transplacental transmission of the organism can also occur; no distinct pattern of teratogenicity has been recorded.¹⁵⁹ Infection with *Borrelia*

has been reported in a few HIV-infected individuals, but it remains unknown whether the concurrent infection alters the disease as it does with another spirochetosis, syphilis.¹⁶⁰

Real-time PCR has been used to detect *Borrelia* in blood samples.¹⁶¹

ERYTHEMA MIGRANS

Erythema migrans, formerly known as erythema chronicum migrans, is the distinctive cutaneous lesion of the multisystem tick-borne spirochetosis Lyme disease (named after the community in Connecticut, where many cases were originally recognized).^{148,162–166} From 20 to 50% or more of the patients have extracutaneous signs or symptoms that may involve the joints, nervous system, and heart.^{167–170} The cutaneous lesion is a centrifugally spreading erythematous lesion at the site of the bite of the tick, *Ixodes scapularis* (*Ixodes dammini*), or other species such as *I. ricinus* in Great Britain.^{166,171} The annular lesion, which measures 5–20 cm in diameter, develops within 3 months of the tick bite (average, 9 days).¹⁷² It can be confused clinically with other annular dermatoses.¹⁷³ Uncommonly, the primary lesion may be vesicular.¹⁷⁴ The risk of infection appears to be low if the tick has been attached for less than 24 hours.¹⁷⁵ Lesions are multiple in up to 25% of cases.^{162,176,177} These other lesions (secondary erythema migrans) result from hematogenous dissemination of the organism.¹⁷⁸ Immunosuppression does not appear to influence the clinical presentation (other than the site of lesions), response to therapy, or production of antibodies to *Borrelia*. The trunk is the favored site of lesions in immunosuppressed patients, and the legs are the favored site in immunocompetent patients.¹⁷⁹

There has been recent debate on the appropriate nomenclature for the various manifestations of this borreliosis. ‘Erythema migrans’ should be used for the cutaneous lesion(s) and ‘Lyme disease’ for the multisystem disease, usually associated with multiple skin lesions, resulting from blood-borne disease.^{180,181}

All three genospecies of *B. burgdorferi* have been isolated from the vector and from some patients with Lyme disease,^{180,182–184} and antibodies and lymphoproliferative responses to it have been found in the sera of patients with the disease.^{185–187} Confirmation of *B. burgdorferi* infection is still only found in approximately 30% of the presumptive cases.¹⁴⁹ Even 40% of culture-positive cases remain seronegative.¹⁸⁶ The diagnosis of erythema migrans is often made by PCR performed on paraffin-embedded biopsy material,¹⁸⁹ although culture is also an important diagnostic tool.¹⁷³ Focus floating microscopy (see later) has been mentioned as the new ‘gold standard’ for diagnosis.¹⁹⁰ The organism usually disappears from lesional skin after treatment with various antibiotics such as doxycycline and the synthetic penicillins.^{191–193} There is evidence that patients with erythema migrans who show persistence of Lyme borreliosis symptoms despite treatment have a decreased Th1 inflammatory response (as assessed by decreased expression of interferon- γ) in involved skin in early stages of the infection.¹⁹⁴ Antibiotics appear to prevent or limit long-term complications such as acrodermatitis chronica atrophicans.¹⁹⁵ Antibody titers are inappropriate for the assessment of therapeutic response because they may persist if the initial skin lesion was large.¹⁹⁶ The organisms may be isolated using BSK-II (Barbour–Stoenner–Kelly) medium.^{172,197,198}

Various methods have been proposed for the prevention of Lyme disease.¹⁹⁹ A vaccine is currently the only empirically demonstrated method to prevent it.¹⁹⁹ Doxycycline therapy following a tick bite appears to have limited success.²⁰⁰

Further studies are required to determine the exact cause of the erythema migrans-like rashes associated with bites of the lone star tick (*Amblyomma americanum*). It is possible that the bites of this tick transmit other, as yet unidentified, spirochetes.²⁰¹ There are some differences in clinical presentation between patients with erythema migrans due to *B. burgdorferi* and those due to *B. garinii*: patients

Figure 24.11 Erythema migrans. A perivascular and interstitial infiltrate is present in the dermis, with lymphocytes being the predominant cell type in this example. (H&E)

Figure 24.12 Erythema migrans. A higher power view of another case, showing lymphocytes, macrophages, and eosinophils; plasma cells are difficult to identify. This biopsy was likely obtained close to the site of the initial tick bite. (H&E)

with the latter tend to have larger lesions, with more central clearing, whereas those with *B. burgdorferi* infection were more apt to have multiple lesions, systemic symptoms, and other abnormal physical findings.²⁰²

Histopathology

There is a superficial and deep perivascular and interstitial infiltrate of lymphocytes, sometimes with abundant plasma cells and eosinophils (Fig. 24.11).²⁰³ Plasma cells are an inconsistent finding.¹⁸⁹ Eosinophils are only prominent adjacent to the site of the initial tick bite (Fig. 24.12).¹⁴⁸ Rarely, there are scattered neutrophils. A study by Wilson *et al.* found that not all biopsy specimens from lesions of erythema migrans show this precise combination of features. Other features noted in confirmed cases of erythema migrans include eosinophils and neutrophils at the periphery of the expanding annular lesion, focal interface change,

spongiosis, inflammation limited to the superficial vascular plexus, and an absence of plasma cells.²⁰⁴ In more than half of the cases, the infiltrate extends into the subcutis. The dermal infiltrate can be equally sparse or moderately dense to dense.¹⁸⁹ When heavy, the infiltrate is more likely to involve the subcutis. Pseudolymphomatous features with germinal centers are uncommon. Interstitial histiocytes (CD68⁺) are common and perivascular dendritic cells much less frequent.¹⁸⁹ Other epidermal changes include apoptotic keratinocytes and lymphocyte exocytosis.¹⁸⁹ With the Warthin–Starry silver stain, a spirochete can be found in nearly half of the specimens in the papillary dermis near the dermoepidermal junction.^{205–207} The diagnosis requires an index of suspicion based on the clinical features. The small size of the organism places some limits on its identification using conventional microscopic techniques.¹⁹⁸ The diagnosis has also been confirmed using an indirect immunofluorescence technique with a monoclonal antibody to the axial filaments of several *Borrelia* species.²⁰⁸ Monoclonal antibodies can also be used in immunoperoxidase techniques. A technique that uses PCR allows the molecular detection of *B. burgdorferi* in formalin-fixed paraffin-embedded lesions of this condition.^{189,209,210}

Focus floating microscopy (FFM) has been described as the new ‘gold standard’ for the diagnosis of cutaneous borreliosis.¹⁹⁰ It detected organisms in 30 of 32 cases of erythema migrans. This immunohistochemical method involves staining sections with a *B. burgdorferi* antibody and then simultaneously scanning sections through two planes, using standard histological equipment.¹⁹⁰ FFM ‘scans through the sections in 2 planes: horizontally in serpentine as in routine cytology and, simultaneously, vertically by focusing through the thickness of the cut (usually 3–4 μm)’.¹⁹¹

Differential diagnosis

Erythema migrans has overlapping features with other conditions characterized by superficial and deep perivascular infiltrates, including photodermatoses, secondary syphilis, and other annular erythemas. In contrast to erythema migrans, erythema annulare centrifugum tends to show a tightly ‘coat-sleeved’ perivascular infiltrate with minimal interstitial inflammation, and plasma cells are generally not a feature. Plasma cells are usually, but not invariably, found in lesions of secondary syphilis. Examples of erythema migrans with vacuolar alteration of the basilar layer, a superficial perivascular lymphocytic infiltrate without plasma cells, and possibly eosinophils would require inclusion of drug eruption, viral exanthem, or id reactions in the list of diagnostic possibilities. Staining for *Borrelia* can be helpful if positive, but in the author’s experience, silver stains are often disappointing. There can be considerable background staining with these methods; *Borrelia* organisms in tissue sections often have wavy rather than tightly coiled contours, and therefore they tend to be overlooked or misinterpreted. Better results can be obtained with specific immunoperoxidase methods if available, but often the pathologist can only suggest the diagnosis, which can then be confirmed by serologic methods.

ACRODERMATITIS CHRONICA ATROPHICANS

Acrodermatitis chronica atrophicans is a chronic/late manifestation of infection by a genospecies of *B. burgdorferi*. *Borrelia afzelii* is the predominant, but not exclusive, etiologic agent.¹⁵⁰ The condition is most often reported from northern, central, and eastern Europe, but not from North America, where *B. afzelii* is not endemic.^{184,211–213} In one report from an endemic area of borreliosis in northern Italy, it was found in 2.1% of patients who had Lyme borreliosis.²¹⁴ There are reports of this condition being preceded by erythema migrans.

Acrodermatitis chronica atrophicans usually occurs in the elderly and is rare in childhood.^{215–218} The diagnosis is often delayed in children.²¹⁷ There is a predilection for females. Clinically, there is an initial inflammatory stage characterized by diffuse or localized erythema,

which gradually spreads to involve the extensor surfaces of the extremities and areas around joints.^{211,219} After some months, there is gradual atrophy of the skin, with loss of appendages and often hypopigmentation. Areas resembling lichen sclerosus et atrophicus, sclerodermatous patches, and linear fibrotic bands over the ulna and tibia may also be found. In addition, juxta-articular fibrous nodules may develop in 10–25% of cases of acrodermatitis chronica atrophicans;^{220,221} they regress rapidly under antibiotic therapy.²²² Neuroborreliosis may result in callosities and plantar ulcers with associated peripheral neuropathy.²¹⁸

Borrelia afzelii DNA has been identified in cutaneous lesions, using PCR, and by culture.^{223,224} The organisms are able to invade endothelial cells, fibroblasts, and Langerhans cells and to survive in collagenous tissue causing tissue damage, resulting in acrodermatitis chronica atrophicans.²²⁴

Various mechanisms have been postulated to explain why borreliae can survive in the collagen for months or years despite the presence of high antibody titers against the organism and the presence of CD4⁺ T lymphocytes. The significant downregulation of major histocompatibility complex class II molecules on epidermal Langerhans cells in both early and late stages of Lyme borreliosis indicates a poorly effective immune response and may partly explain the faulty elimination of the organisms from the skin.^{224,225} A study has shown a restricted pattern of cytokine expression in this condition. Whereas interferon- γ is produced in lesions of erythema migrans, it is lacking in acrodermatitis chronica atrophicans.²²⁶ This cytokine may play a role in spirochetal killing.²²⁶

Histopathology

The early stages of the disease show a superficial and deep chronic inflammatory cell infiltrate in the dermis that is moderately heavy and composed predominantly of lymphocytes with some histiocytes and plasma cells. There is often accentuation around blood vessels, which may show telangiectasia, and also around adnexae. Sometimes there is a superficial band-like infiltrate of inflammatory cells with a thin zone of collagen separating the inflammatory cells from the basal layer. Scattered vacuoles or groups of vacuoles that morphologically resemble fat cells (but that do not appear to stain for fat – pseudolipomatosis cutis) have been reported in the upper dermis in some cases (see p. 1018).²¹¹ As the lesions progress, there will be atrophy of the dermis to approximately half its normal thickness or less (Fig. 24.13). This is usually accompanied by loss of elastic fibers and pilosebaceous follicles, atrophy of the subcutis, and variable epidermal atrophy with loss of the rete pegs.²¹²

Other changes that may be found include diffuse dermal edema, a subepidermal edematous or sclerotic zone, basal vacuolar change, hyperkeratosis, and changes resembling lichen sclerosus et atrophicus. Dense dermal sclerosis may be seen in the sclerodermatous patches. The juxta-articular fibrous nodules show broad bundles of homogeneous collagen in the upper subcutis enclosing islands of fatty tissue.²²² There is a perivascular and interstitial infiltrate of lymphocytes and plasma cells.²²² Some examples of acrodermatitis chronica atrophicans have shown pseudolymphomatous infiltrates, with two different microscopic configurations: one has a band-like superficial dermal infiltrate with exocytosis and a fibrotic papillary dermis, resembling mycosis fungoides, and another shows a dense, nodular dermal lymphoplasmacytic infiltrate without germinal center formation. Of eight cases with a mycosis fungoides-like configuration, the one tested showed a polyclonal T-cell receptor gene rearrangement; of three cases with nodular dermal infiltrates, all expressed both κ and λ light chains with a polyclonal pattern.²²⁷

In 2003, another distinctive histopathological pattern was described in cutaneous borreliosis.²²⁸ It was thought to be an intermediate-stage lesion with clinical features suggestive of morphea. The

Figure 24.13 Acrodermatitis chronica atrophicans. There is some atrophy of the dermis. (H&E)

histopathological features were similar in all 11 cases reported and consisted of an interstitial inflammatory infiltrate, predominantly of histiocytes dispersed among the collagen reminiscent of the interstitial form of granuloma annulare. There were focal areas with a pseudorosette pattern resulting from small histiocytes arranged radially around

thick collagen bundles.²²⁸ In some cases, a few plasma cells were present in the infiltrate – a feature not seen in granuloma annulare.

Electron microscopy

Degenerative changes have been reported in collagen, elastic tissue, and nerve fibers.²¹²

BORRELIA-ASSOCIATED LYMPHOCYTOMA CUTIS

In endemic regions, *B. burgdorferi* is the principal causative agent for lymphocytoma cutis, a cutaneous B-cell pseudolymphoma. This entity is considered in Chapter 41 with other cutaneous lymphocytic infiltrates. Of the 106 patients studied at the University of Graz (Austria), 63 cases involved the nipple,²²⁹ whereas another European study found evidence of *Borrelia* infection in 47% of 56 cases with lymphoid hyperplasia of the nipple.²³⁰ The earlobe was another common site.

Interferon- α -2A can be used to treat this condition in patients unresponsive to antibiotics.²³¹

Histopathology²³⁰

The condition is characterized by dense lymphoid infiltrates with prominent germinal centers. Atypical features are common in the germinal centers. A few cases may morphologically simulate a large B-cell lymphoma. A monoclonal band is rarely detected using PCR analysis of the IgH gene rearrangement.²²⁹ Long-term follow-up suggests that a few cases do progress to B-cell lymphoma.²³¹

BORRELIA-ASSOCIATED B-CELL LYMPHOMA

The occurrence of lymphoma in skin affected by acrodermatitis chronica atrophicans has been known for some time. More recently, *B. burgdorferi* has been identified by culture, or by detection of specific DNA, in up to 20% of cases of cutaneous B-cell lymphoma (see p. 1193).^{232,233} Some of the cases reported previously as pseudolymphoma and associated with *B. burgdorferi* are probably low-grade lymphomas akin to the marginal zone lymphomas associated with *Helicobacter pylori* infection. However, *Borrelia*-associated lymphocytoma cutis (pseudolymphoma) can closely simulate a primary cutaneous large B-cell lymphoma, and it has been suggested that antibiotic therapy should be considered in suspected cases of primary cutaneous B-cell lymphoma in regions with endemic *B. burgdorferi* infection.²³⁴

INTRODUCTION

Fungal infections of the skin are an important category of cutaneous disease. Included in this chapter are the dermatophytes, which produce countless millions of skin infections each year, and the systemic and related mycoses whose clinical importance usually pertains to their involvement of organs other than the skin. This category assumes life-threatening importance in immunosuppressed individuals, a significant group being those suffering from HIV/AIDS. Organ transplant recipients are another important group. The mycoses are of global importance. The advent of new topical and systemic therapies in approximately the past decade has been of great importance in the control of these infections.

The mycoses have long been a confusing area for anyone with only a peripheral interest in mycology. Classifications have been modified repeatedly, and some fungi have undergone several changes in nomenclature in the space of a decade. The classification of the various fungal infections of the skin usually takes into account some of the morphological characteristics of the fungus concerned, as well as the distribution and nature of the infection that results. This approach has some shortcomings. For example, tinea nigra could be classified as either a superficial filamentous infection or a dematiaceous fungal infection. Sporotrichosis is considered in this account with the dematiaceous fungi because of some clinical and histological overlap with chromomycosis. However, the yeast form in tissue sections is not pigmented, although the fungi are dematiaceous in culture. Members of the genus *Alternaria* are occasionally implicated as agents of phaeohyphomycosis; their colonies are gray to black, although they are not pigmented in tissues.¹ Against this background is the plea for a simplification of the nomenclature and the avoidance of fungal names as part of the clinical nomenclature to avoid confusion when the name of the organism is subject to change as a consequence of taxonomic reclassification.² This seems to occur not infrequently. For example, the organism that causes pityrosporum folliculitis is now known as *Malassezia*.

Fungal identification

Fungi grow slowly on laboratory media and their final identification, which is based on the appearance of their colonies and conidia in culture, as well as other characteristics, can take several weeks.³ Accordingly, direct examination of tissue specimens is often undertaken in conjunction with histopathological examination of biopsy material in order to obtain a more rapid diagnosis.

The most widely used of these techniques, which is of most value in the examination of skin scrapings, is the application of a drop of 10% potassium hydroxide (KOH) to a slide containing the material. This usually clears the tissues in approximately 5 minutes, allowing fungi to be more easily visualized. It is our practice to use a solution that combines KOH with glycerol (to prevent drying out) and calcofluor white, an agent that imparts a bright fluorescence to fungi when examined with a fluorescence microscope. If Chicago sky blue 6B is used with KOH as the clearing agent, a standard microscope can be used to examine the scraping. It is particularly useful for the identification of *Malassezia furfur*, but it can be used for dermatophytoses.⁴

There are several methods of identifying fungi in paraffin-embedded material. Many fungi, particularly the dematiaceous and hyaline fungi, are readily visible in sections stained with hematoxylin and eosin (H&E). Some difficulty may be experienced with *Candida*, *Cryptococcus*, *Aspergillus*, *Blastomyces*, *Coccidioides*, and *Mucor*.⁵ Numerous sections may have to be examined in sporotrichosis to find fungal elements, and in most cases recourse to other stains (see later) is more practical. The dermatophytes are also difficult to see in sections stained with H&E, but they can sometimes be made visible by racking down the condenser and reducing the light.

Various special stains can be used in an attempt to identify fungi in tissue sections. The periodic acid–Schiff (PAS) stain, sometimes combined with diastase digestion, is most frequently employed. It stains the cell walls of fungi a purple color of varying intensity. The silver methenamine (methenamine silver) stain, usually Grocott's modification, is a reliable method of detecting fungi: it stains them black against a green background. It is more reliable than the PAS stain for detecting degenerate fungal elements and the rare animal pathogens among the aquatic fungi, although it may be less reliable with zygomycetes.⁶ Unfortunately, it stains some structures in inflammatory debris, making fungal identification difficult in some circumstances. These two stains have been regarded as broad-spectrum stains because they are positive across a wide range of fungi.⁷ Some stains highlight only certain organisms and not others. These so-called narrow-spectrum stains can be used as an adjunct to fungal identification.^{7,8} *Cryptococcus neoformans* may be stained with the mucicarmine stain or a combined Alcian blue–PAS stain, which shows the cell wall and capsule in contrasting colors.⁹ It is usually doubly refractile under polarized light. It also stains with the Masson–Fontana method. These narrow-spectrum stains are discussed further in the relevant fungal disease.

Calcofluor white can be used to stain frozen or paraffin sections as well as tissue smears.⁶ The sections must be viewed with a fluorescence microscope. Certain fungi are even autofluorescent when a section stained with H&E is exposed to ultraviolet light.⁵ These include *Blastomyces*, *Cryptococcus*, *Candida*, *Aspergillus*, *Coccidioides*, and occasionally *Histoplasma*.^{5,10}

An antiserum containing a polyclonal antibody to *Mycobacterium bovis* has been used with immunohistochemical techniques to identify a broad range of bacteria and fungi in paraffin-embedded tissue. This method seems to be particularly useful when organisms are sparse.¹¹

The use of immunoperoxidase techniques and special fungal antibodies for the detection and diagnosis of fungi in smears and paraffin sections has been described.¹² The fungi stain a golden brown against a pale blue background. The technique is sensitive and specific. A major disadvantage is that most laboratories are unlikely to have available a comprehensive reference collection of fungal antibodies for use in this technique.

Polymerase chain reaction (PCR)-based techniques are now being used to identify specific species of fungi, including dermatophytes.^{13–15} They have revealed marked genetic diversity among some fungi, particularly *Trichophyton mentagrophytes*.¹⁶ Nested PCR is a further accurate method for rapid identification of dermatophytes in clinical specimens. Unfortunately, it has a high false-negative rate.¹⁷ Real-time PCR assay, using dermatophyte gene-sequence records, is a highly sensitive method for the detection/identification of common dermatophyte infections.¹⁸ PCR amplification combined with restriction enzyme analysis may also be used.¹⁹

The majority of cutaneous mycoses are superficial infections caused by dermatophytes and various yeasts. The dermatophytoses are considered first.

SUPERFICIAL FILAMENTOUS INFECTIONS

Two groups of fungal infections are included in this category: the dermatophytoses and the dermatomycoses. They are characterized by the presence of filamentous forms of the organism in tissue sections.

DERMATOPHYTOSSES

The dermatophytes are a group of related filamentous fungi that have the ability to invade and colonize the keratinized tissues of humans and animals.^{20–22} Infections caused by these fungi, which account for 3

or 4% of dermatological consultations, are known as dermatophytoses (ringworm, tinea).^{23,24}

The clinical appearances are quite variable and depend on a number of factors, including the species of fungus, the site of infection, the immunological status of the patient, and the prior misuse of topical steroids.^{25,26} The usual appearance on glabrous skin is an erythematous (and sometimes vesicular) annular centrifugally growing lesion, with peripheral scale and desquamation and central clearing.^{23,27} Broken hairs and dystrophic nails occur with infections involving these structures. Less common presentations include subcutaneous and deep dermal infections (dermatophytic granuloma, pseudomycetoma)^{28–36} and abscesses,^{37–40} verrucous lesions,²⁶ granular parakeratosis,⁴¹ blastomycosis-like lesions,⁴² and rarely lymphogenous or hematogenous extension.⁴³ Lymph node involvement may accompany deep dermatophytosis.⁴⁴ Immunocompromised individuals are usually involved with these atypical presentations.^{30,40,45–48} Lesions known as favus, kerion,⁴⁹ and Majocchi's granuloma also occur, and these are described later. The atypical presentations that may follow the use of topical steroids have been called 'tinea incognito'.^{25,50,51}

Chronic persisting infections, defined on the basis of duration or treatment failure, also occur. Disturbed cellular immune functions have been found in many of these cases. Diabetes mellitus, palmo-plantar keratoderma,⁵² ichthyosis,⁵³ atopic states, collagen diseases, and Cushing's syndrome may all predispose to chronic and recurrent dermatophyte infections;⁵⁴ so too may HIV infection.⁵⁵ Despite these findings, a study of patients infected with HIV found no increase in the prevalence of uncomplicated dermatophyte infection.⁵⁶

A secondary allergic eruption ('id reaction') may develop, uncommonly, in patients with dermatophyte infections, particularly tinea pedis.²⁷ The id reaction (autoeczematization) is usually vesicular and on the palms (see p. 127); it may be more generalized. Erythema nodosum, vasculitis, and erythema multiforme are other rare reactions to dermatophytes.²⁷

Mycology

Dermatophytes belong to three genera: *Epidermophyton*, *Microsporum*, and *Trichophyton*. There are three ecological groups of dermatophytes according to their natural habitats: anthropophilic, which preferentially affect humans; zoophilic, in which lower animals are the prime hosts; and geophilic, which live in the soil as saprophytes.^{3,20} There is geographic variability in the distribution of fungi, although some species are widely distributed throughout the world.⁵⁷ The most common isolate is the anthropophilic fungus *T. rubrum*, which accounts for 40% or more of all dermatophyte infections worldwide.^{54,58–60} Other common isolates include *T. violaceum*^{61,62} (particularly in Africa and Europe, but not America), *T. mentagrophytes*, *T. tonsurans*, *E. floccosum*, *M. gypseum*,^{63,64} *M. canis*, and *M. audouinii*.⁶⁵ The last two species are declining in incidence, whereas infections caused by *T. rubrum* and *T. tonsurans* are on the increase.^{57,66,67} The zoophilic fungi, such as *M. audouinii*, *M. canis*, *T. verrucosum*,⁶⁸ and *T. tonsurans*, more commonly affect children and tend to evoke a more acute inflammatory response than do the anthropophilic fungi.²⁷ *Microsporum canis* has been isolated from a neonate in an intensive care unit.⁶⁹ In a study from Riyadh, Saudi Arabia, *T. mentagrophytes* and *M. canis* were the most common dermatophytes responsible for infections.⁷⁰

Less common dermatophyte isolates of geographical or occupational interest include *T. soudanense*^{71,72} (found in Africa and sometimes in travelers), *T. concentricum*^{73–75} (the cause of tinea imbricata in the South Pacific and tropical America), *T. erinacei*⁷⁶ (from hedgehogs), *M. nanum*⁷⁷ (from swine), *T. simii*⁷⁸ (from monkeys), and *M. equinum*⁷⁹ and *T. equinum*^{80,81} (from horses). Mixed isolates, sometimes including a yeast, occur.

The development of infection depends on exposure to an affected source and various factors diminishing host resistance. Associated

diseases that predispose to dermatophyte infections were mentioned previously.⁵⁴ Local predisposing factors include abrasion, occlusive dressings, sweating, maceration, and poor peripheral circulation.⁵⁴ The immunological mechanisms involved in eliminating dermatophytes are poorly understood. Acute infections are associated with good cell-mediated immunity, the short-term development of specific antibodies, and the onset of delayed hypersensitivity.²⁷ Chronic infections, in which *T. rubrum* is commonly implicated,⁸² are associated with poor *in vitro* cell-mediated immunity and sometimes elevated levels of IgE.^{83–85} Deep dermal invasion by this organism has also been reported in immunosuppressed patients.⁴⁷ The dermatophyte itself may sometimes be the cause of the immunosuppression, which results from a serum factor found in widespread dermatophytosis.⁸⁶ Resistance to antifungal therapy does not appear to play a role in these chronic infections.⁸⁷ There is no apparent HLA predilection to dermatophyte infections,⁸⁸ although it has been suggested that chronic *T. rubrum* infection (discussed previously) occurs as a specific syndrome involving 'susceptible' hosts.^{53,89} Chronic *T. rubrum* infection has been associated with severe measles in a young female due to suppression of cell-mediated immunity caused by the fungal infection.⁹⁰ A 2003 study concluded that renal transplant recipients were not at increased risk of dermatophytosis, but they were at increased risk to opportunistic infections with *Pityrosporum ovale* and *Candida albicans*.⁹¹

Specific regional infections

Traditionally, dermatophyte infections of the skin have been considered on the basis of the site of involvement because there are often some features unique to each. The subtypes considered are tinea capitis (including favus and kerion), tinea faciei, tinea barbae, tinea corporis, tinea cruris, tinea pedis, and onychomycosis. Majocchi's granuloma is usually considered as a discrete entity. Tinea gladiatorum, found in wrestlers who have close body contact, may result in tinea corporis or tinea capitis; it is not considered further.^{92–95} Contact sports, such as judo, are also associated with a higher incidence of dermatophyte infection.⁹⁶

Tinea capitis

Scalp ringworm or tinea capitis has become an increasingly important public health problem in recent years.^{97,98} It was once almost exclusively an infection of children, and it was associated with either *M. canis* or *M. audouinii*.^{99–101} *Microsporum canis* is the causative organism in only 10% of all tinea capitis infections in the United Kingdom.¹⁰² This organism is still common in some countries.¹⁰³ Tinea capitis due to *M. vanbreuseghemii* has recently been reported; it produces an ectothrix infection.¹⁰⁴ Now, *T. tonsurans* and *T. violaceum* are the most common isolates in some geographical areas,^{105–123} causing an endothrix type of hair invasion with the fungus entering the cortex just above the hair bulb and encircling the shaft beneath an intact cuticle.¹²⁴ Endothrix infections do not produce fluorescence with Wood's light, as opposed to ectothrix infections (*M. canis* and *M. audouinii*), which give a typical green fluorescence. *T. rubrum*, the commonest cause of tinea corporis, is not usually regarded as a scalp pathogen, although very occasional cases occur.^{125–127} *Trichophyton soudanense* is a common cause of tinea capitis in Africa; it is rare elsewhere except in immigrants from Africa.^{128–130} The effects vary from mild erythema with persistent scaliness and minimal hair loss to inflammatory lesions with pustules and folliculitis and kerion formation.^{131,132} Scaly papules and plaques of the ears (helix, antihelix, retroauricular region) represent a sign (the 'ear sign') that is highly specific although not very sensitive for the diagnosis of tinea capitis in children.¹³³ Adults generally present with alopecia and scale,¹³⁴ but it may also masquerade as a bacterial pyoderma.^{135,136} Tinea capitis may also mimic dissecting cellulitis.¹³⁷ Tinea capitis seems to be surprisingly rare in patients with

HIV infection.^{138,139} It is also uncommon in the first year of life.^{140–142} Transmission at the hairdresser has been recorded in two elderly women.¹⁴³ Household contacts are a potential reservoir of infection.¹⁴⁴ The production of extracellular proteases by the fungi facilitates their dissemination through the stratum corneum of the scalp.¹⁴⁵ Dermoscopic examination of tinea capitis shows several types of distorted hair shaft: comma hairs,^{146–148} corkscrew hairs,^{149–151} and broken, dystrophic hairs.^{149,150} Corkscrew hairs have been reported to disappear following successful treatment of *T. violaceum*-induced tinea capitis with griseofulvin.¹⁵²

Kerion

A kerion is a boggy violaceous inflammatory area of dermal suppuration and folliculitis.^{49,153–156} It is most common on the scalp but can be produced in other sites,^{157,158} as an occupational hazard, by zoophilic fungi. *Trichophyton verrucosum* and *T. tonsurans*, both endothrix fungi, are often implicated in the etiology of a kerion. *Trichophyton rubrum*,^{159–161} *T. mentagrophytes*,¹⁶² and *T. erinacei*^{163,164} are rare isolates. *Trichophyton violaceum*, an endothrix fungus, is the most common cause of kerion in northern Tunisia.¹⁶⁵ This type of infection has also been reported from *Arthroderma benhamiae*, a teleomorph of *T. mentagrophytes*,¹⁶⁶ and (in Sri Lanka) *A. incurvatum*, a teleomorph of *M. gypseum*¹⁶⁷ (a teleomorph represents the sexual reproductive stage of certain fungi). Kerion is the result of a hypersensitivity reaction to the dermatophyte infection.¹⁶⁸ If early treatment is not started, a scarring alopecia may result.¹⁶⁸

Favus

Favus (tinea capitis favosa) is a chronic infection of the scalp, sometimes involving glabrous skin, that is typically acquired in childhood¹⁶⁹ but can occur in adults.¹⁷⁰ The infection can persist for life. It has been associated with disseminated cancer.¹⁷¹ It is most characteristic of infection with *T. schoenleinii*, although it has also been associated with *T. violaceum*, *T. verrucosum*, *T. mentagrophytes*, *M. canis*, and *M. gypseum*.^{64,169,170,172} In this form, there are scaly, crusted, yellowish plaques with concave shape, known as *scutula*. Microscopic examination of cultures of *T. schoenleinii* show characteristic antler-like filaments known as favic chandeliers.¹⁷⁰

Tinea faciei

Tinea faciei is an uncommon regional variant presenting as a facial erythema with scaling.^{173,174} Diagnosis is often delayed. *Trichophyton rubrum*,¹⁷³ *T. mentagrophytes*,¹⁷⁵ *M. gypseum*,¹⁷⁶ and *T. tonsurans*¹⁷⁷ have been implicated. *Microsporum canis* is the organism primarily responsible for tinea faciei among children in Cagliari, the capital of Sardinia, Italy.¹⁷⁸ A recent case was due to *T. erinacei*.¹⁷⁹ Clinically, it may mimic cutaneous lupus erythematosus, rosacea, polymorphic light eruption, granuloma faciale, lupus vulgaris, seborrheic dermatitis, or granuloma annulare.^{180,181} Cases may rarely mimic granuloma faciale¹⁸² or cutaneous lupus erythematosus histologically,¹⁸⁰ in another case, abscess formation occurred.¹⁸³

Tinea barbae, tinea corporis, and tinea cruris

Tinea barbae, tinea corporis, and tinea cruris have overlapping clinical features.¹⁸⁴ The usual organisms involved are *T. rubrum*,^{185,186} *T. mentagrophytes*, and *E. floccosum*.⁵⁴ Teleomorphs of *T. mentagrophytes* may also cause tinea corporis.¹⁸⁷ A case of tinea corporis due to *M. gallinae* has been reported from Japan; this is a zoophilic fungus most closely associated with chickens but occasionally causing human disease.¹⁸⁸ Mixed infections are sometimes recorded.¹⁸⁹ *Epidermophyton floccosum* particularly involves the groin region and is common in closed

communities because it is easily shed. It is unable to invade hair. A kerion-like tinea barbae caused by *T. rubrum* has been associated with erythema nodosum.¹⁹⁰ A photoexacerbated tinea corporis mimicking subacute lupus erythematosus has also been reported.¹⁹¹ Tinea cruris occurs almost exclusively in males, and unusual clinical appearances have been noted in patients with AIDS.^{192,193} Penile involvement as an isolated lesion is exceedingly rare.¹⁹⁴ Familial disease has also been reported.¹⁹⁵ Diaper dermatitis is a variant that predominantly affects infants between 7 and 12 months of age.¹⁹⁶ **Tinea imbricata** is a special type of tinea corporis in which there are concentric rings of scale.¹⁹⁷ It is a chronic infection that occurs in the West Pacific and South American regions; it is caused by *T. concentricum*.^{73,198,199} *Trichophyton tonsurans* and *T. mentagrophytes* infections may rarely mimic tinea imbricata.^{200,201} The term 'radiation port dermatophytosis' is used for cases of tinea corporis localized to irradiated skin.^{202,203}

Tinea pedis (athlete's foot)

Tinea pedis is the most common regional dermatophytosis in adolescents and adults. *Trichophyton rubrum* and *T. mentagrophytes* var. *interdigitale* are the most common isolates.^{204,205} Rare cases of interdigital intertrigo due to species of *Fusarium* have been reported.²⁰⁶ The appearances are often modified by maceration and fissuring, but the sharp scaling border is usually preserved. Maceration predisposes to bacterial overgrowth. Once these bacteria propagate, fungi, which initiated the infection, cannot usually be recovered via culture.²⁰⁷ Tinea pedis is also associated with increased production of the antimicrobial peptide human β -defensin-2, but obviously it does not prevent concurrent bacterial infection in some cases of tinea pedis.²⁰⁸ Vesicles and pustular lesions are sometimes seen.^{209,210} Tinea pedis is common in swimmers,²¹¹ military personnel,²¹² marathon runners,²¹³ and in some male worshippers who practice communal ablution and subsequent prayer in bare feet.²¹⁴ It is increased in hematological malignancies.²¹⁵ Unilateral lesions of the sole have been reported in children.²¹⁶ Tinea pedis may not be more common in patients with psoriasis, as once thought.²¹⁷

Tinea manuum (tinea of the palms) is usually accompanied by tinea pedis and onychomycosis. In the majority of cases, it is caused by *T. rubrum*, but other organisms have been involved.²¹⁸

Majocchi's granuloma

The term 'Majocchi's granuloma' is given to nodular and plaque-like lesions of the lower leg, most common in females and showing a histological picture of a granulomatous perifolliculitis.^{219,220} Various fungi have been implicated, including *T. rubrum*,²²¹ *M. canis*,²¹⁹ *T. violaceum*, *T. tonsurans*,²²² *T. mentagrophytes*, and *Aspergillus fumigatus*.²²³ The terms 'nodular granulomatous perifolliculitis' and 'trichophytic granuloma' have been used for comparable lesions on the calf and scalp, respectively. Trichophytic granulomas, which are often nodular and in the subcutis, may occur in sites other than the scalp.³¹ The condition often occurs in immunocompromised individuals.^{224,225}

Onychomycosis

Onychomycosis is a fungal infection of the nail characterized by thickening, splitting, roughening, and discoloration of the nail.²²⁶ Its incidence is increasing worldwide; its prevalence in Europe may be as high as 26.9%.²²⁷ It accounts for nearly 30% of all superficial fungal infections of the skin and for up to 50% of all onychopathies.²²⁸ Some 50–80% or more cases of onychomycosis are caused by dermatophytes.²²⁹ The remainder result from yeasts, particularly *C. albicans*, and various molds, such as *Scytalidium dimidiatum*, *Scopulariopsis brevicaulis*, *Fusarium* sp., *Acremonium* sp., *Alternaria* sp., and *Aspergillus* sp.^{230–236} Diagnosis of onychomycosis due to nondermatophyte

molds can be difficult because the organisms involved are common contaminants. Criteria for diagnosis include KOH preparation for direct microscopy, isolation of the organism in culture, repeated isolation in culture, inoculum count, failure to identify a dermatophyte in culture, and histopathology.²³⁷ Dermatophytes mainly involve the toenails, with *T. rubrum* and, to a lesser extent, *T. mentagrophytes* var. *interdigitale* being the usual agents.^{226,238–240} The foot acts as a fungal reservoir;²²⁹ tinea pedis is also present in one-third of patients with toenail onychomycosis.²⁴¹ Various immunological disturbances and peripheral vascular disease may predispose to infection. Slow nail growth is not a predisposing factor for onychomycosis.²⁴² Psoriasis appears to constitute a risk factor for dermatophyte infections of the nail but not for all categories of onychomycosis.²⁴³ Onychomycosis is a serious health burden, particularly in older persons and diabetics.^{244–247} Behavioral factors such as sporting and certain religious practices predispose to onychomycosis.²²⁸ Extensive whitening of the nails due to *T. rubrum* has been reported in a patient with AIDS.²⁴⁸ *Trichophyton rubrum* infection may also have a genetic basis, with autosomal dominant spread in some families.²⁴⁹ Children with Down syndrome have a predisposition to this condition.²⁵⁰

The majority of infections caused by *C. albicans* and other species of *Candida* involve the fingers. The soft tissues around the nail are involved first, producing a paronychia with secondary penetration of the keratin by the fungus.^{251,252} Because *Candida* is not keratolytic, it tends to occur in situations of frequent water immersions and immunosuppressed states.²²⁹

Clinically, dermatophyte infections of the nail have traditionally been divided into distal, lateral, proximal, and white superficial variants according to the anatomical localization and appearances.²⁵³ A new classification, expanding on this traditional one, has been proposed.²⁵⁴ Its categories are distal and lateral subungual, superficial, proximal subungual, endonyx, and total dystrophic.²⁵⁴ Fungal infection may also involve the nail isthmus.²⁵⁵ In superficial white onychomycosis (SWO), invasion of the nail plate is assumed to occur from the dorsal surface.²⁵⁶ This mode of infection is not universal because SWO can be combined with other categories of onychomycosis. This has led to a new classification system proposing four subtypes of SWO. Whereas the superficial variants are usually due to *T. mentagrophytes* var. *digitale* (but not in all countries),²⁵⁷ the ‘deep’ subtype may be due to molds.^{226,258,259} In the case of proximal subungual onychomycosis, it has been suggested that some cases may be the consequence of lymphatic dissemination of the fungus.²⁶⁰ A case of this variant caused by *M. gypseum* has been reported.²⁶¹ The occurrence of these different types of SWO appears to reflect differing host–parasite relationships. The variants are not pathogen specific.²²⁶

The fungal elements occur mostly in the deeper portions of the nail plate and in the hyperkeratotic nail bed rather than on the surface of the nail plate.^{262,263} Sometimes a thick hyperkeratotic nodule forms beneath the nail. This contains numerous clumped hyphae (dermatophytoma).^{264,265} This is an explanation for the negative results obtained from scrapings in some cases of onychomycosis. Although mycological culture is the ‘gold standard’ for the diagnosis of onychomycosis,²⁶⁶ histopathological examination of the nail using the PAS stain is still the most sensitive diagnostic method^{267–270} but the least cost-effective procedure.²⁷¹ A KOH preparation stained with chlorazol black E is said to be most cost-effective.²⁷¹ A study from Hideko Kamino’s group in New York found that the vast majority of cases (97%) of onychomycosis can be diagnosed by histological examination of subungual hyperkeratosis only, avoiding the time-consuming process of softening of the nail plate.²⁷² Pretreatment of nails with sodium hydroxide prior to processing for histopathologic examination can also improve the quality of tissue sections and improve adherence to glass slides.²⁷³ Excellent results in diagnosing onychomycosis have also been obtained with use of the Chicago sky blue stain.²⁷⁴ Because fungi are found by PAS stain in only 60% of morphologically abnormal nails, it is important not to

assume that a fungal infection is present in all such nails and commence expensive treatments ‘on spec’.^{252,275} Clinical clues to onychomycosis being the cause of a nail dystrophy include dystrophy confined to the third or fifth toenails on the same foot, unilateral dystrophy, and male gender.²⁷⁶ A clinical rule has been developed for the diagnosis of onychomycosis.²⁷⁷ Findings predicting the presence of fungus are previous diagnosis of fungal disease, plantar desquamation involving more than 25% of the sole, the presence of interdigital tinea, and consideration by a dermatologist that onychomycosis is the most probable diagnosis.²⁷⁷ Among the new diagnostic methods being developed for onychomycosis are two microscopic methods – optical coherence tomography²⁷⁸ and phase-contrast hard X-ray microscopy using synchrotron radiation²⁷⁹ – and a method of analysis of protein patterns in nail samples, using matrix-assisted laser desorption/ionization time-of-flight mass spectrometry.²⁸⁰

Treatment of dermatophyte infections of the skin and nails involves the use of terbinafine, itraconazole, and griseofulvin, with one or other of these therapies proving more effective than others in different regional variants and with different dermatophytes. Topical therapy can be used for localized cutaneous lesions. Otherwise, oral therapy is the treatment of choice. Griseofulvin, terbinafine, itraconazole, and fluconazole have similar efficacy rates and side effects in infections due to *Trichophyton* species; the last three agents require a shorter duration of treatment but are more expensive than griseofulvin. Griseofulvin is still regarded as the treatment of choice for infections due to *Microsporum* species because it is more effective than terbinafine and cheaper than itraconazole and fluconazole.²⁸¹ For *tinea pedis*, treatments include topical terbinafine (more effective than topical azoles in one study),²⁸¹ oral terbinafine,²⁸² pramiconazole (also useful for tinea cruris/corporis),²⁸³ and luliconazole, which appears to be particularly useful in interdigital tinea pedis.²⁸⁴ In *onychomycosis*, terbinafine tablets, itraconazole capsules, griseofulvin, and ciclopirox nail lacquer are approved by the U.S. Food and Drug Administration.²⁸¹ True superficial white onychomycosis, restricted to the dorsum of the nail, will respond to topical antifungal therapy, but any extension of the infection and other clinical subtypes require systemic therapy.^{285,286} Itraconazole and terbinafine are safe and effective in childhood cases.²⁸⁷ Some of the molds are resistant to the usual antifungal drugs.²⁸⁸ Nails may have a persistently abnormal appearance, even when treatment has been effective.²⁸⁹ Toenail onychomycosis has also been successfully treated with photodynamic therapy.²⁹⁰ Griseofulvin and terbinafine have been effective in *tinea imbricata*, whereas itraconazole and fluconazole have not.¹⁹⁷ Single case reports have noted successful use of oral terbinafine for childhood *kerion*,¹⁶² oral and topical terbinafine for *tinea faciei* caused by *T. equinum*,⁸¹ and combined oral griseofulvin and topical selenium sulfide for *T. soudanese* infection.¹²⁸

Histopathology of dermatophytoses

Biopsy material from dermatophyte infections can show a wide range of histological changes.²⁹¹ Ackerman elaborated three different changes in the stratum corneum that can be associated with dermatophyte infections: the presence of neutrophils,²⁹² compact orthokeratosis (Fig. 25.1),²⁹³ and the presence of the ‘sandwich sign’.²⁹⁴ The last refers to the presence of hyphae ‘sandwiched in’ between an upper but normal basket-weave stratum corneum and a lower layer of recently produced stratum corneum that is abnormal in being compact orthokeratotic or parakeratotic in type.²⁹⁴ The presence of neutrophils in the stratum corneum was not regarded as a reliable sign of dermatophytosis in one study from Vancouver.²⁹⁵ The presence of neutrophils should always result in the performance of the PAS stain if it has not already been performed as a routine procedure. Gomori methenamine silver (GMS) stain is also effective for demonstrating the organisms (Fig. 25.2). Uncommonly, the stratum corneum retains its normal basket-weave pattern.

Figure 25.1 Dermatophyte infection. Hyphae are present in the compact orthokeratotic layer. (H&E)

Figure 25.2 Dermatophyte infection. Hyphae are well demonstrated with Gomori methenamine silver stain. (GMS)

The epidermis is often mildly spongiotic; more florid spongiotic vesiculation is usually present when the palms and soles are involved. Subcorneal or intraepidermal pustulation is a less common pattern (Fig. 25.3).²⁹¹ Chronic lesions show variable acanthosis (Fig. 25.4). The dermis shows mild superficial edema and a sparse perivascular infiltrate, which includes lymphocytes and occasionally eosinophils or neutrophils.

Occasionally, the dermal infiltrate is much heavier, particularly if there is follicular involvement (Fig. 25.5). There may be perifollicular neutrophils or a mixed inflammatory infiltrate (Fig. 25.6). In tinea capitis, fungal organisms that are found in or around hair shafts do not penetrate further down the infected hair than the zone where the nucleated hair shaft completely cornifies and becomes hard keratin (also the zone of complete keratinization of the cuticle and Henle's layer of the inner root sheath). This zone, which forms an inverted 'V', is known as Adamson's fringe.²⁹⁶ There is a heavy inflammatory infiltrate in a kerion, with the proportion of the various cells depending on the duration of the lesion. The changes may vary from a suppurative folliculitis to a granulomatous process.¹⁶⁸ In *Majocchi's granuloma*, there are perifollicular and dermal granulomas and chronic inflammation; reactive lymphoid follicles may be present.²²⁰ Fungal elements

Figure 25.3 (A) Dermatophyte infection. (B) Neutrophils are present within the spongiotic vesicle. (H&E)

may take several forms: yeasts, bizarre hyphae, and mucinous coatings.²²⁰ Fungal elements are sometimes sparse.²⁹⁷

Rare patterns of inflammation include a resemblance to granuloma faciale, papular urticaria, or eosinophilic pustular folliculitis.²⁹⁸ In immunocompromised patients, large numbers of hyphae and pseudospores are present in areas of dermal necrosis.^{26,45} The lesions often lack granulomas, a point of distinction from the usual Majocchi's granuloma (discussed previously).

Dermatophytes exist in tissues in a parasitic form characterized by branched, septate hyphae and small spores. Methods for their identification were mentioned previously. It has been claimed and subsequently refuted that the dendrites of Langerhans cells are PAS positive and can be seen in the stratum corneum of lichenoid dermatitides.²⁹⁹ The importance of performing a routine PAS stain on all inflammatory skin diseases has been stressed. Hyphal elements were present in one study in only 57% of PAS-positive cases of tinea on H&E sections alone.³⁰⁰ It is also cost-effective to do routine PAS stains on all inflammatory skin diseases.³⁰¹ Automatic staining procedures are easy to establish. A study found that the GMS stain was superior to the PAS stain for the routine diagnosis of onychomycosis.³⁰²

Dermatophytes may invade the hair shaft (endothrix infection) or remain confined to its surface (ectothrix infection). *Trichophyton tonsurans*, *T. violaceum*, and *T. soudanense* are true endothrix parasites.³⁰³

Figure 25.4 *Tinea imbricata*. There are numerous hyphae and some spores in the thickened stratum corneum. The underlying epidermis shows psoriasiform hyperplasia. (H&E)

Figure 25.5 Folliculitis with suppuration resulting from a dermatophyte infection. (H&E)

Dermoscopy of the nail plate (onychoscopy) can be useful in identifying distal subungual onychomycosis by identifying two signs that are unique to this form of onychomycosis (a jagged edge with spikes at the proximal margin of the onycholytic area and longitudinal striae) and one sign characteristic of traumatic onycholysis (a linear edge at the proximal margin of the onycholytic area).³⁰⁴

Differential diagnosis

A diagnosis of dermatophytosis requires an index of suspicion, followed by careful search and, if necessary, performance of PAS or GMS stains. Fungal organisms are not seen in areas of parakeratosis, probably due to the rapid epithelial turnover in these areas. Although most commonly the background changes in dermatophytosis are those of spongiotic dermatitis, a wide variety of reaction patterns can be associated with dermatophyte infections. For example, reaction patterns associated with *T. rubrum* infection alone can resemble erythema multiforme, erythema perstans, purpuric dermatitis, granuloma faciale, granuloma annulare, pustular dermatitis, and papulonecrotic dermatitis with allergic angiitis, in addition to forms of spongiotic dermatitis.²⁹¹ Examples of tinea faciei may rarely mimic granuloma faciale¹⁸² or

cutaneous lupus erythematosus histologically.¹⁸⁰ Fungal folliculitis must be distinguished from other forms of inflammatory and/or scarring alopecia. Majocchi's granuloma can resemble folliculitis with follicular rupture due to a variety of causes, including primary acneiform folliculitis or bacterial folliculitis. Miller and Bhawan reported two examples of bullous tinea pedis (both of which showed intraepidermal vesiculation and numerous hyphae within the stratum corneum) with positive basement membrane zone C3 deposition on direct immunofluorescence.³⁰⁵ The authors noted that linear/granular basement membrane zone fluorescence with various immunoreactants can be encountered in other unexpected situations, including graft-versus-host disease, lichen planus, erythema multiforme, bullous fixed drug eruption, bullous drug eruption—not otherwise specified, acrokeratosis paraneoplastica, Hailey–Hailey disease, acquired cutis laxa, and sun-exposed skin.³⁰⁵

On dermoscopy, the finding of broken hairs, comma hairs, and corkscrew hairs allows distinction from alopecia areata, which in contrast shows yellow dots (a reflection of the dilated infundibula of anagen and telogen follicles), exclamation point hairs, and vellus hairs.¹⁵⁰

Figure 25.6 Tinea capitis. (A) There is a sparse perifollicular inflammatory cell infiltrate and numerous fungal elements involving the hair. (H&E) (B) Fungal elements can be seen within the hair shaft (endothrix infection). (Grocott stain)

DERMATOMYCOSES

The term 'dermatomycoses' encompasses infections of the hair, nails, or skin caused by nondermatophytes that have filamentous forms in tissues. It covers such infections as tinea nigra, piedra, pityriasis versicolor, and candidosis.

Infections caused by the molds *Scytalidium dimidiatum* (the anamorphic form of *Nattrassia mangiferae*, formerly known as *Hendersonula toruloidea*)^{306,307} and *Scytalidium hyalinum*³⁰⁸ are included as dermatomycoses. They are increasingly important as a cause of onychomycosis and tinea pedis.^{288,309,310} They have been reported in patients with coexistent systemic disease such as lupus erythematosus, diabetes mellitus, cancer,³¹¹ and dyskeratosis congenita.³¹² They are being isolated with increasing frequency in the United Kingdom and Europe from individuals who have emigrated from tropical regions.^{288,313} There is no orally effective treatment.³¹⁰

Scopulariopsis brevicaulis, a widespread saprophytic fungus, is included here for completeness. It has been associated with onychomycosis and, rarely, chronic granulomatous skin infections.^{314,315} *Saccharomyces cerevisiae* (baker's yeast) is an exceedingly rare cause of systemic and/or cutaneous infection in immunocompromised

patients.³¹⁶ It responded in one case to voriconazole.³¹⁶ Systemic infections with these various organisms have been treated in the past with amphotericin B and fluconazole.

YEAST INFECTIONS

Yeasts are fungi of primarily unicellular growth habit.³¹⁷ The normal vegetative cells of yeasts are round or oval and measure 2.5–6 μm in diameter. Many yeasts can form hyphae or pseudohyphae in cutaneous infections. They are a regular constituent of the normal human flora, but most are potential pathogens. Opportunistic yeast infections increased with the advent of broad-spectrum antibiotics and immunosuppressive therapy.³¹⁸ They are now an important complication in patients with AIDS.

Candida albicans and *Cryptococcus neoformans* are the most important yeasts, producing, respectively, candidosis and cryptococcosis.

Malassezia globosa, previously known as *Malassezia furfur* and *Pityrosporum orbiculare*, produces the cosmetically disfiguring condition pityriasis versicolor (tinea versicolor). *Malassezia* can also produce folliculitis. It has been incriminated in the etiology of confluent and

reticulated papillomatosis and of some cases of seborrheic dermatitis (including its occurrence in patients with AIDS),³¹⁹ dandruff, psoriasis, and atopic dermatitis.^{320–322} It is likely that the organisms are present because of the favorable ‘soil’ in these conditions.

Trichosporon sp. can produce both white piedra, a superficial infection of the hair, and a disseminated infection in immunosuppressed patients. It is discussed later in this section.

The genera *Rhodotorula*,³¹⁸ *Torulopsis*,³¹⁸ and *Sporobolomyces*³²³ are of little importance in relation to the skin and are not considered further.

CANDIDOSIS (CANDIDIASIS)

Candida albicans is the most frequent species of *Candida* implicated in human infections. These range from relatively trivial superficial infections to fatal disseminated disease.^{324–326} *Candida albicans* is a normal inhabitant of the gastrointestinal tract and is found in the mouths of 40% of normal individuals. It is sometimes isolated from the skin surface, but it is not a usual constituent of the skin flora. Many factors predispose to clinical infection, including pregnancy,³²⁷ the neonatal period, immunological and endocrine dysfunction, antibiotic therapy, and immunocompromised and debilitating states.³²⁴ Local factors such as increased skin moisture and heat also play a role. Studies have provided a better understanding of the various factors that contribute to the invasive properties of *C. albicans*.³²⁸ For example, the yeast can express at least three types of surface adhesion molecules to colonize epithelial surfaces, in addition to an aspartyl proteinase enzyme that facilitates penetration of keratinized cells.³²⁸

A number of clinical variants of candidosis occur: acute superficial candidosis, chronic mucocutaneous candidosis, systemic (disseminated) candidosis, and candidosis in the infant.³²⁴ Oral, periungual, and genital candidosis are best regarded as distinct entities that may occur alone or in association with other clinical forms of candidosis. Folliculitis and delayed surgical wound healing are rare manifestations of *Candida* infection.^{329,330} *Candida* folliculitis may mimic tinea barbae.^{331,332} Another species of *Candida*, *C. parapsilosis*, can sometimes cause localized and systemic infections in immunocompromised patients and after extensive burns. It has also been responsible for a chondritis after surgery to the ear.³³³

Acute superficial candidosis

Acute superficial candidosis is the usual form of cutaneous infection with *Candida* species. There are vesicles, pustules, and crusted erosions with a beefy-red appearance. These develop on skin folds and other areas, particularly in individuals living in a humid environment.³²⁴ The condition may be self-limited; it responds well to treatment. Decubital candidosis is a variant of cutaneous candidosis that occurs on the dorsal skin of chronically bedridden patients; often there has been long-term use of antibiotics. It does not seem to predispose to disseminated (systemic) candidosis.³³⁴

Histopathology

The characteristic histological feature is the presence of neutrophils in the stratum corneum. The infiltration may take the form of small collections of cells, spongiform pustulation, or subcorneal pustulation resembling impetigo. The underlying epidermis may show focal spongiosis and mild acanthosis. Fungal elements may be sparse. They are best visualized with the PAS stain. They can also be demonstrated with the GMS stain but not the Congo red stain.⁸ Mycelia predominate over spores. Electron microscopy has shown that the majority of the fungal elements are inside the epithelial cells.^{335,336}

Chronic mucocutaneous candidosis

The term ‘chronic mucocutaneous candidosis’ covers a heterogeneous group of disorders characterized by chronic and persistent infections of the mucous membranes and also infections of the skin and nails by various species of *Candida*, usually *C. albicans*.^{337–340} The condition ranges in severity from a mild localized and persistent infection of the mouth, nails, or vulva to a severe generalized condition.³²⁴ It may be associated with a spectrum of cellular immunodeficiency states, including several defined syndromes that range from life-threatening to subtle.³³⁸ A deficiency of the cytokine interleukin-2 (IL-2) was present in one case.³⁴¹ Other cytokines are also involved, and it now appears that the basic defect is altered cytokine production in response to *Candida* antigens.³⁴² Other associations include endocrinopathies and nutritional deficiencies, the latter including disorders of iron metabolism.^{324,338,343} On the basis of recent cases, it appears that there are two *Candida* endocrinopathy syndromes, one associated with hypoparathyroidism and/or hypoadrenalism^{344,345} and the other associated with hypothyroidism. The former is inherited as an autosomal dominant trait and the latter syndrome as an autosomal recessive trait.³⁴⁶ This inheritance is at odds with the OMIM gene map that lists chronic mucocutaneous candidosis with thyroid disease (OMIM 606415) as an autosomal dominant condition linked to chromosome 2p. Candidosis with hypoparathyroidism and/or Addison’s disease (OMIM 240300) is now called the autoimmune polyendocrine syndrome, type 1, and it is caused by a mutation in the autoimmune regulator gene (*AIRE*) linked to chromosome 21q22.3.^{347,348} Autoantibodies to cytokines provide a possible explanation for some forms of chronic mucocutaneous candidosis. For example, autoantibodies targeting the T-cell cytokines IL-17 and IL-22 are strongly associated with chronic candidal infection in autoimmune polyendocrinopathy syndrome.^{349–351} Two further familial chronic mucocutaneous candidosis syndromes include an autosomal dominant form without endocrine disease (OMIM 114580) and a very rare form with only nail candidosis and intercellular adhesion molecule-1 (ICAM-1) deficiency (OMIM 607644).³⁵² Late onset of chronic mucocutaneous candidosis in adults is rare and usually associated with cancer, particularly a thymoma.^{338,353} It has also been associated with hyperimmunoglobulin E syndrome.³⁵⁴ Agammaglobulinemia is a further recently described association.³⁵⁵ Autosomal dominant chronic mucocutaneous candidosis has been associated with mutations of the *STAT1* (signal transducers and activators of transcription) gene, resulting in defective Th1 and Th17 responses.^{356–359}

In all clinical groups, vaginitis, paronychia, and oral thrush may also be present. The cutaneous lesions are asymptomatic plaques on the dorsum of the hands and feet and periorificial skin.³⁵³ They are brown-red with sharp margins and a soft scale.³⁵³ Sometimes a more extensive scaling eruption is present. Nail dystrophy may occur.^{360,361} Granulomatous lesions have been recorded.³⁶² In 20% of all cases, there is a concurrent dermatophyte infection.^{343,353} Antigliadin antibodies were present in one case.³⁶³

Because of the chronicity of the condition, a diverse range of topical and oral antifungal treatments has been used. Azole antifungal agents (ketoconazole, itraconazole, and fluconazole) are often used, but recurrence of the disease occurs after cessation of the drug.^{361,363} Amphotericin B was used prior to the introduction of azole drugs.

Histopathology

There is some histological resemblance to the acute form, although the lesions tend to have more epidermal acanthosis, sometimes being vaguely psoriasiform in type (Fig. 25.7). There may be areas of compact orthokeratosis²⁹³ and others of scale crust formation with degenerating neutrophils. This reflects the chronicity of the lesions. Spores and hyphae can sometimes be observed in H&E-stained sections and are usually found without difficulty in PAS preparations (Fig. 25.8).

Figure 25.7 Chronic candidosis. (A) There is mild psoriasiform hyperplasia of the epidermis. (B) There is overlying scale crust containing degenerate neutrophils. (H&E)

Figure 25.8 Chronic candidosis. (A) In this example, spores, hyphae, and pseudohyphae can be identified in H&E-stained sections. (H&E) (B) PAS staining highlights organisms in the stratum corneum. (PAS)

In granulomatous lesions, there are vaguely formed granulomas in the dermis composed of lymphocytes, plasma cells, epithelioid cells, and occasional Langhans giant cells. Occasional yeast forms and pseudohyphae may be found in the granulomas.

Disseminated candidosis

Disseminated (systemic) candidosis is increasingly being recognized in immunosuppressed and debilitated patients and in patients with hematological disorders and neutropenia, particularly those with central venous catheters and those receiving broad-spectrum antibiotics.^{324,264–367} Multisystem involvement occurs, although cutaneous lesions are present in only 15% of cases.³⁶⁵ *Candida tropicalis* is a frequent isolate from the cutaneous lesions in this type of candidosis.^{367,368} Severe exacerbation of disseminated candidosis has followed treatment with granulocyte colony-stimulating factor.³⁶⁹

There is an erythematous papulonodular rash, with multiple lesions on the trunk and proximal parts of the extremities. The face and distal extremities may also be involved.³⁶⁷ Sometimes only isolated lesions

are present. Other rare clinical presentations mimic ecthyma gangrenosum^{370,371} and leukocytoclastic vasculitis.²⁷² The mortality rate in one series was 84.2%.³⁶⁷

Systemic candidosis is well recognized in heroin addicts, but only comparatively recently have cutaneous lesions, in the form of folliculitis, been reported in some addicts.^{373,374}

Treatment with amphotericin B and/or fluconazole has been used. However, disseminated candidosis has actually developed despite fluconazole prophylaxis in a small intestine transplant recipient.³⁷⁵

Histopathology

There are small microabscesses in the upper dermis, sometimes centered on blood vessels.³⁶⁵ A few budding yeasts may be found in these areas on a PAS stain.³⁶⁵ A dense, mixed dermal and subcutaneous inflammatory infiltrate has also been described.³⁷⁶ At other times, the reaction is much milder, with only a perivascular mixed inflammatory cell infiltrate. A leukocytoclastic angiitis has been reported.³⁶⁸ In lesions resembling ecthyma gangrenosum, the papillae are edematous and distended by numerous pseudohyphae, which may extend into vessel walls.³⁷¹ Ulceration is also present. In heroin addicts, there is a suppurative folliculitis and perifolliculitis. Pseudohyphae are sometimes found within the hair.

Candidosis of the newborn

There are several distinct clinicopathological entities within this group: congenital cutaneous candidosis, neonatal candidosis, and infantile gluteal granuloma.³²⁴ Immunity is not impaired.

Congenital cutaneous candidosis presents at birth or during the first days of life with generalized erythematous macules and papulopustules.^{377,378} It results from intrauterine infection.^{379,380} Organisms may be demonstrated in the placenta and in the stratum corneum of the neonatal lesions.³⁷⁹

Neonatal candidosis presents with oral and perioral lesions in the first 2 weeks of life.³⁷⁹ Infection is probably acquired during intravaginal passage at the time of delivery.³⁷⁹ Sometimes there is involvement of the diaper area.³⁷⁹ Severe, so-called 'invasive fungal dermatitis' is a rare form of cutaneous fungal infection occurring in neonates weighing less than 1000 grams.³⁸¹

Infantile gluteal granuloma (granuloma gluteale infantum) is an etiologically controversial entity characterized by discrete granulomatous lesions in the diaper (napkin) area.³⁸² Diaper dermatitis is part of the spectrum.^{383,384} The role of *Candida* is uncertain.^{324,382,385} The use of topical fluorinated steroids and plastic pants in infants with diaper dermatitis has been incriminated.^{382,386} Rarely, a similar entity has been reported in this region in adults, possibly as a consequence of *Candida* infection.³⁸⁷ Biopsy of a recent infantile case showed parakeratosis, moderate and somewhat psoriasiform acanthosis, spongiosis with exocytosis, and a moderate perivascular round cell infiltrate; special stains were negative for *Candida* organisms.³⁸⁸

Oral candidosis

Oral candidosis (thrush) is found mostly in infants as irregular white patches and plaques.^{324,389} It can also be found as part of chronic mucocutaneous candidosis and in debilitated adults on long-term antibiotics or with a hematological malignancy. Rarely, thrush is related to poor oral hygiene and dentures.³⁹⁰ Oral candidosis has been reported as an initial manifestation of AIDS.³⁹¹

Other patterns of mucosal involvement occur on the tongue. These include median rhomboid glossitis³⁹² and black hairy tongue, although the latter has been attributed to species of *Candida* other than *C. albicans*.³²⁴ A perioral pustular eruption has been ascribed to *Candida*.³⁹³

Epithelial hyperplasia is a characteristic feature of mucosal infection.

Genital candidosis

Vaginal candidosis is a common gynecological infection.³⁹⁴ It tends to occur in the absence of other lesions. A thick creamy vaginal discharge is present. Sexual transmission of the infection sometimes occurs, but balanitis is much less common than vulvovaginitis.³⁹⁴

Periungual candidosis

Paronychia may occur as an isolated infection, particularly in women who frequently immerse their hands in water.³⁹⁵ Minor mechanical trauma, diabetes, and circulatory disturbances may also be incriminated.³²⁴ The nail of the middle finger of the dominant hand is most frequently involved.³⁹⁵ In chronic mucocutaneous candidosis, there is usually onychodystrophy with nail bed deformity rather than onycholysis, which is more often a manifestation of acute infection.

CRYPTOCOCCOSIS

Cryptococcus neoformans (formerly known as *Torula histolytica*) is an encapsulated yeast-like fungus found in dried avian (particularly pigeon) and bat excreta and also in dust contaminated with such droppings.^{396–400} Its usual portal of entry is the respiratory tract, leading to the formation of pulmonary granulomas. Meningoencephalitis is another clinical presentation of cryptococcosis. Hematogenous dissemination leading to cutaneous involvement occurs in approximately 10–15% of cases of cryptococcosis. Another frequently isolated species is *Cryptococcus gattii*,⁴⁰¹ which is found in wood debris and tends to infect immunocompetent individuals.⁴⁰² *Cryptococcus laurentii* is a rare human pathogen.⁴⁰³

Skin lesions may be the first evidence of an occult systemic infection.^{404,405} Although many cases have been reported as instances of primary cutaneous cryptococcosis,⁴⁰⁶ probably only a few of these have resulted from primary inoculation of organisms into the skin, thereby fulfilling the criteria of a true primary cutaneous infection.^{407–411} Preceding trauma has sometimes been implicated in primary cutaneous disease.^{412,413} Most patients are immunocompromised,^{414–422} and the infection is now a well-recognized occurrence in patients with AIDS.^{423–431} With improving antiretroviral therapy for patients with AIDS, organ transplant recipients are now at the highest risk of acquiring cryptococcosis. The risk in transplant recipients is 2.6–2.8%.^{432,433} The new immune modulator drugs have been associated with localized and disseminated disease.^{432,434,435} The cutaneous presentations of cryptococcosis are protean and include papulonodules, ulcers, pustules, plaques, ecchymoses, cellulitis, and subcutaneous abscesses.^{436–440} Lesions may rarely simulate pyoderma gangrenosum,⁴⁴¹ herpes,^{423,442} keloids,⁴⁴³ or molluscum contagiosum.^{425,426,442,444} Any site may be involved, but there is a predilection for the face, neck, and forearms.⁴¹⁰

Concurrent infection with alternariosis has been reported.⁴⁴⁵ In another case, leprosy was the associated infection.⁴⁴⁶

A rapid diagnosis may be made by examination of India ink preparations of aspirates or Tzanck smears.⁴³² The organisms are readily isolated on Sabouraud's agar. Rarely, other species of *Cryptococcus* have been isolated from infected tissues.^{447,448}

Histopathology^{398,449}

The histology is variable, ranging from tuberculoid granulomas in the dermis and upper subcutis, with few organisms, to lesions in which large numbers of the yeast-like organisms, surrounded by their mucinous capsular material, form extensive mucoid masses (Figs. 25.9–25.11).⁴¹⁴ The organisms mostly range from 5 to 15 µm in diameter. A common pattern is a dense infiltrate of chronic inflammatory cells with multinucleate giant cells containing several organisms with refractile walls. Focal granulomas may be present, as may some small spaces

Figure 25.9 Cryptococcosis. (A) Granulomas and sheets of inflammatory cells in the dermis. (B), (C) Numerous yeasts in macrophages and giant cells. (H&E)

containing numerous organisms, both free and in macrophages. Palisaded granulomas are rare.⁴⁵⁰ One case of trauma-induced *Cryptococcus gattii* infection in an immunocompetent patient showed an abscess surrounded by a palisade of multinucleated giant cells and a lymphomononuclear infiltrate.⁴⁰² A few neutrophils are often present; small microabscesses are less common. The overlying epidermis may show acanthosis, mild pseudoepitheliomatous hyperplasia, or ulceration. Transepidermal elimination of organisms may be seen.³⁹⁶

Cryptococcal inflammatory pseudotumors have been described in HIV-positive patients.⁴⁵¹ There was a storiform arrangement of spindle cells, in addition to spindle and polygonal cells that were arranged in a haphazard manner.⁴⁵¹ There were scattered lymphocytes, plasma cells, and giant cells. Focal necrosis and some fibrosis were also present. Immunophenotyping of the spindle cells showed a mixed histiocytic and myofibroblastic lineage, with a predominance of histiocytes.⁴⁵¹

The cell wall of *Cryptococcus neoformans* will stain with the PAS or silver methenamine methods, and the capsule will stain with mucicarmine or Alcian blue.³⁹⁶ Because the cell walls of *Cryptococcus* contain melanin, they can be stained with methods such as Fontana-Masson, which can be helpful in outlining capsule-deficient organisms.⁴⁵² A combined PAS-Alcian blue stain that contrasts the cell wall and capsule is a useful method. The Alcian blue staining of *Cryptococcus* is shared only with *Pityrosporum* and, to a lesser degree, *Blastomyces*.⁷ *Cryptococcus* does not stain with Congo red, as occurs with

Pityrosporum.⁷ Phagocytosed organisms often have an attenuated capsule that does not stain. Nonencapsulated tissue variants⁴⁵³ and hyphal forms have been described in other sites. The latter are found only very rarely and usually only in superficial ulcerated lesions at the body orifices. The organism is usually doubly refractile under polarized light. It may be confirmed by the use of indirect immunoperoxidase methods on routine paraffin sections.⁴⁵⁴ Typing of the isolate by PCR fingerprinting using available primers can also be performed.⁴⁵⁵

Electron microscopy

The organisms have an electron-dense wall and a surrounding clear space, beyond which is the capsule.⁴¹⁵ In some phagocytosed organisms, the capsule has been destroyed and there is only a small amount of fibrillary material remaining.⁴⁴⁹ Projecting buds may be seen, even on phagocytosed organisms.^{449,456}

Differential diagnosis

The 'gelatinous' variant of cryptococcosis in patients who are immunodeficient has a characteristic microscopic appearance. Generally, in situations in which some capsular material is present, mucin stains are positive, thereby identifying a characteristic feature of this organism. Capsule-deficient organisms in tissue sections from immunocompetent patients, which as might be expected also show a host

Figure 25.10 Cryptococcosis. (A) Extension into bone and joint is occurring in this amputated finger. (B) There is a mucinous area with numerous organisms and a surrounding inflammatory palisade. (H&E)

Figure 25.11 Cryptococcosis. Numerous gray-appearing yeast forms are surrounded by mucinous capsular material. This biopsy was from an HIV-positive patient. (H&E)

inflammatory reaction, can create significant diagnostic difficulties because the organisms vary considerably in size. They can thereby potentially mimic *Histoplasma capsulatum*, microforms of *Blastomyces dermatitidis*, and, less commonly, *Candida* species or incompletely developed *Coccidioides immitis* spherules. In difficult situations,

distinction can be made by direct immunofluorescence using specific *Cryptococcus neoformans* antibodies, PCR methods, or electron microscopy (because even 'capsule-deficient' cells can be shown to have attenuated capsules with this method). Fontana–Masson staining is also helpful (see previous discussion) in that positive staining of the cell walls excludes *Blastomyces* and *Histoplasma*. However, note that *Sporothrix schenckii* and incompletely developed spherules of *Coccidioides immitis* can also stain with this method.⁴⁵⁷

PITYRIASIS VERSICOLOR

Pityriasis versicolor (tinea versicolor) is a relatively common noncontagious superficial fungal infection, usually located on the upper trunk or upper arms.^{458–460} It is both chronic and recurrent. Its prevalence in a group of young Italian sailors was 2.1%,⁴⁶¹ whereas in a group of Italian pregnant women it was 5.7%, which was said to compare with a 2–5% prevalence in temperate climates.⁴⁶² Lesions are slightly scaly and may be macular, nummular, or confluent. They vary in color from red-brown to white, and the scales show yellow fluorescence with Wood's light.⁴⁵⁸ Suspected lesions that are not overtly scaly may produce scale when the surrounding skin is stretched, a maneuver called the 'evoked scale sign'.⁴⁶³ Hair loss or thinning can sometimes be observed within the lesions.⁴⁶⁴ Infections are more common in patients with seborrheic dermatitis, dandruff,⁴⁶⁵ or hyperhidrosis and in residents in the tropics.⁴⁵⁶ Involvement of the nipple has been attributed to the increased concentration of sebaceous glands in that region⁴⁶⁶ and/or localized seborrhea.⁴⁶⁷ Increased sweating may account for the occurrence of lesions in the flexures.⁴⁶⁸ In infants, a papulopustular eruption of the cephalic area (neonatal acne) may result from infection with the same fungus.⁴⁶⁹ Colonization of neonatal skin by species of *Malassezia* is common (30% at 2–4 weeks of age) so that care must be taken in attributing any neonatal disease to its presence.⁴⁷⁰ It is now thought that it does not cause neonatal cephalic pustulosis (neonatal acne),⁴⁷⁰ despite earlier reports suggesting an association.⁴⁷¹ A rare atrophic variant of pityriasis versicolor, at times mimicking mycosis fungoides or anetoderma clinically, has been reported. In the past, prior treatment with topical corticosteroids had been suspected to be the mechanism in these cases, preferentially affecting lesional skin because of the decreased barrier function associated with superficial *Malassezia* infection.⁴⁷² There is indeed diminished barrier function in lesional skin of pityriasis versicolor, as assessed by transepidermal water loss.⁴⁷³ However, among the cases of atrophic pityriasis versicolor described by Crowson and Magro,⁴⁷⁴ prior corticosteroids had been used in only 1 of the 12 patients. The pathogenesis of these lesions is unclear, although possible mechanisms have been proposed.⁴⁷⁴ Lesions resembling pityriasis rotunda (see p. 290) have also been reported.⁴⁷⁵ In another case, overlapping parallel scales resembling tinea imbricata were present.⁴⁷⁶ One subgroup of atopic dermatitis (head and neck dermatitis) can be aggravated by *Malassezia* sp.^{477,478} Although affected patients have a normal cell-mediated immune response to the organism, they do not generate a protective response to mycelial antigens.⁴⁷⁹ Finally, pityriasis versicolor has been associated with the use of etanercept therapy.⁴⁸⁰

The causative organism, previously called *Malassezia furfur*, is a dimorphic lipophilic fungus that is a normal inhabitant of the stratum corneum and infundibulum of the hair follicle.^{481–483} The yeast phase of this organism has two morphologically discrete forms: an ovoid form, known for decades as *Pityrosporum ovale*, and a spherical form, *Pityrosporum orbiculare*.⁴⁸⁴ Each form can transform into the other. A taxonomic revision of the genus *Malassezia* was carried out in 1996 with the description of four new species: *M. globosa*, *M. restricta*, *M. obtusa*, and *M. slooffiae*. *Malassezia sympodialis* and *M. pachydermatis* had been described earlier, the latter being regarded as a resident of animal skin.⁴⁸⁵ Since that time, three more species have been

appended to the genus: *M. dermatis*, *M. japonica*, and *M. nana*.³²¹ The following summary details our current knowledge. It is likely to change as more studies accumulate from both tropical and temperate climates.

- *M. globosa* – pityriasis versicolor and healthy skin
- *M. sympodialis* – normal skin, particularly trunk; has produced pityriasis versicolor circinata⁴⁸⁶
- *M. restricta* – seborrheic dermatitis and dandruff³²²
- *M. pachydermatis* – cats and dogs; systemic infection in premature infants
- *M. slooffiae* – normal skin; low number of isolates
- *M. obtusa* – rare isolate; little known about it
- *M. dermatis* – isolated from patients with atopic dermatitis in Japan
- *M. japonica* – as for *M. dermatis*
- *M. nana* – an animal isolate.

In a study of patients from subtropical Argentina, *M. sympodialis* and *M. globosa* were the most prevalent species, but also identified (with or without co-infection with other *Malassezia* species) were *M. furfur*, *M. slooffiae*, *M. restricta*, *M. dermatis*, and *M. pachydermatis*.⁴⁸⁷

Based on results from relatively recent studies, it now appears that pityriasis versicolor is caused by *M. globosa* in its mycelial phase.⁴⁸⁵

Hypopigmentation in pityriasis versicolor (pityriasis versicolor alba) results from the production of dicarboxylic acids by the organisms.⁴⁸⁸ These have a tyrosinase inhibitor effect, thus interfering with the synthesis of melanin.^{489,490} Confetti-like hypopigmentation has been reported.⁴⁹¹ **Hyperpigmentation** may result in part from the production of large melanosomes, singly distributed,⁴⁹² but also from vascular hyperemia, orthokeratosis, and the presence of organisms.^{493,494}

Lesions of pityriasis versicolor have the interesting property of retaining topically applied gentian violet, a procedure that has been called ‘*in vivo* Gram staining’ (because the mechanism of the Gram stain is retention of gentian violet (crystal violet) by ‘gram-positive’ organisms).⁴⁹⁵ Uninvolved skin stains less intensely, and potentially confounding lesions such as pityriasis rosea, atopic dermatitis, and vitiligo apparently do not retain gentian violet.⁴⁹⁵

Pityriasis versicolor may be treated with topical or oral antifungal agents, the latter being used for widespread disease or failed topical therapy.⁴⁹⁶ The triazoles (itraconazole, ketoconazole, and fluconazole) are often used in therapy.⁴⁹⁶ Successful treatment of the disease using photodynamic therapy with 5-aminolevulinic acid has been reported.⁴⁹⁷

Histopathology

There is slight to moderate hyperkeratosis and acanthosis. The dermis contains a mild, superficial perivascular inflammatory infiltrate that includes lymphocytes, histiocytes, and occasional plasma cells. There may be mild melanin incontinence in some cases. In the stratum corneum, there are numerous round budding yeasts (blastomycetia) and short septate hyphae (pseudomycelium), giving a so-called ‘spaghetti and meatballs’ appearance (Fig. 25.12). *Pityrosporum* are clearly seen in H&E and PAS preparations. They also stain with Alcian blue (as does *Cryptococcus*), Congo red (as does *Blastomyces*), and the Masson–Fontana stain (as does *Cryptococcus*).⁷ They are not acid fast. In those cases associated with hair loss or thinning, changes include miniaturization of follicles, dilated infundibula, keratotic plugs, and degenerated hair shafts; hyphae with or without yeast forms are often identified within the follicular lumina and surrounding hair shafts.⁴⁶⁴

One study has shown that helper-inducer T cells dominate among the sparse dermal infiltrate.⁴⁹⁸ These cells may be responsible for the atrophic lesions described by Crowson and Magro (discussed previously) by producing cytokines that interfere with collagen metabolism and/or keratinocyte growth. The lesions described in this report

Figure 25.12 Pityriasis versicolor. (A) Numerous budding yeasts and short hyphae are present in the stratum corneum. (H&E) (B) They can also be seen with special stain. (PAS stain)

showed variable epidermal and dermal atrophy with effacement of the rete ridges, subepidermal fibroplasia, pigment incontinence, and elastolysis.⁴⁷⁴ Another recent report of atrophying pityriasis versicolor also described focally decreased and fragmented dermal elastic fibers.⁴⁹⁹

Electron microscopy

Fungi can be demonstrated at all levels of the stratum corneum, in follicles, and even intracellularly.⁵⁰⁰

Differential diagnosis

Because most biopsies of pityriasis versicolor show minimal or no morphologic abnormalities involving the epidermis or dermis, it qualifies as one of the ‘nothing’ lesions – that is, a group of disparate disorders whose microscopic findings are minimal despite often distinctive clinical features. When faced with this dilemma, systematic evaluation

of the biopsy specimen is indicated to search for subtle abnormalities, beginning with the stratum corneum, where in pityriasis versicolor the characteristic short hyphae and spores can be identified. This unique arrangement of organisms also helps to distinguish pityriasis versicolor from dermatophytosis or candidiasis.

PITYROSPORUM FOLLICULITIS

Pityrosporum folliculitis presents as erythematous follicular papules and pustules, 2–4 mm in diameter, with a predilection for the upper back, shoulders, chest, and upper arms.^{458,501,502} The lesions can be quite pruritic.⁵⁰³ It is more common in females and in those older than age 30 years.⁵⁰⁴ Sometimes there is associated seborrheic dermatitis or pityriasis versicolor.^{501,505} It has been reported in Down syndrome,⁵⁰⁶ pregnancy,⁵⁰⁷ and in immunocompromised patients,^{508,509} in whom it may be confused clinically with more serious infections.⁵¹⁰ It has been reported as a nosocomial infection in three patients in the same intensive care unit.⁵¹¹ *Malassezia furfur* can be cultured from lesions in approximately 75% of cases,⁵⁰¹ and affected individuals have serum antibody titers against this organism.⁵⁰⁵ Using the most recent taxo-

nomic classification, it is likely that *Malassezia globosa* is the organism responsible. There is evidence that follicular occlusion is the primary event in the pathogenesis of this condition, with yeast overgrowth being a secondary occurrence.⁵¹²

Histopathology⁵¹³

Involved follicles are dilated and often plugged with keratinous material and debris. There is a mild chronic inflammatory cell infiltrate around the infundibular portion of the follicle. Intrafollicular deposits of mucin are sometimes present.⁵¹⁴ If serial sections are examined, disruption of the follicular epithelium is sometimes found, with basophilic granular debris, keratinous material, neutrophils, and other inflammatory cells in the perifollicular dermis (Fig. 25.13).⁵¹³ A few foreign body giant cells may also be present when rupture of the follicle has occurred. A PAS or silver methenamine stain will reveal spherical to oval yeast-like organisms, 2–4 μ m in diameter. These organisms are sometimes budding. They are found most often in the follicle, but following rupture they can also be found in the perifollicular inflammatory exudate.⁵¹⁵ Sometimes a few hyphae can also be seen.⁵⁰¹ Pseudo-actinomycotic granules have been reported in two cases.⁵¹⁶

Figure 25.13 Pityrosporum folliculitis. (A) Inflammatory cells and basophilic granular debris are present in the dermis adjacent to the point of rupture of the hair follicle. (H&E) (B) The tiny yeasts can just be seen at this magnification. (PAS stain) (C) Another example, shown at slightly higher magnification. Yeast forms can be seen within the follicular lumen (arrows, and inset). (H&E) Higher magnification of Pityrosporum folliculitis (inset).

Differential diagnosis

Pityrosporum folliculitis is distinguishable from other types of folliculitis by the characteristic dilated or ballooned lumina of involved follicles and the finding of *Pityrosporum* yeast within follicular infundibula.

TRICHOSPORONOSIS AND WHITE PIEDRA

The yeast *Trichosporon asahii* (formerly called *T. beigelii* and *T. cutaneum*) is a rare cause of a generalized blood-borne infection in immunosuppressed patients,⁵¹⁷ particularly those with leukemia or a lymphoma.^{518,519} Trichosporonosis is frequently fatal in this clinical setting.⁵¹⁸ Disseminated infection with *T. inkin* and *H. capsulatum* has been reported in a patient with newly diagnosed AIDS.⁵²⁰ Cutaneous lesions occur in approximately 30% of patients with this infection; lesions take the form of purpuric papules and nodules with central necrosis or ulceration.⁵¹⁷ Isolated skin lesions and hand eczema are exceedingly rare.^{521–524} Primary cutaneous trichosporonosis due to *T. dermatis* has been reported in an immunocompetent man, thought to be due to a puncture wound from an unknown plant; the lesion presented on the foot as an ulcerated nodule that developed fistulous tracts.⁵²⁵ Chronic cutaneous infection with *T. asahii* has been reported in a non-immunocompromised person.⁵²⁶ In one instance, a cutaneous abscess due to this organism occurred at the site of corticosteroid injection into a hypertrophic scar.⁵²⁷ *Trichosporon asahii* is a common cause of onychomycosis and tinea pedis in some countries.^{528,529} Virulence factors associated with *Trichosporon* species include the ability to form biofilms on implanted devices, the presence of glucuronoxylomannan in their cell walls (which may interfere with the phagocytic ability of neutrophils and monocytes), and the production of proteases and lipases.⁵³⁰ Diagnosis of invasive disease is enhanced by PCR methods, Luminex® xMAP® technology (a novel flow cytometric technique), and proteomics, in which protein fingerprint analysis is carried out by mass spectrometry.⁵³⁰

A reclassification of the genus *Trichosporon* has taken place; the 'old' *T. beigelii* has been replaced by at least six species, one of which is *T. asahii*.⁵²² *Trichosporon ovoides*, *T. inkin*, *T. cutaneum*, and *T. loubieri* are the species now considered responsible for white piedra, a rare superficial infection of the hair resulting in white to tan-colored gritty nodules, just visible to the naked eye, along the hair shaft.^{531,532} The scalp, face, or pubic area may be involved. White piedra must be distinguished from black piedra, in which tightly adherent black nodules form on the hair, particularly on the scalp.⁵³³ Black piedra is caused by infection with *Piedraia hortae*, which is not a yeast but an ascomycete. Piedra is discussed further in Chapter 15 (p. 479).

Isolated cutaneous lesions due to *T. asahii* have been treated successfully with oral itraconazole and topical tioconazole cream.⁵²⁴

Histopathology

In fatal systemic infections, numerous slender hyphae and budding yeasts can be seen in the deep dermis and in the walls of blood vessels.^{518,534} The inflammatory response is usually poor because of the underlying neutropenia.⁵¹⁸

In the localized cutaneous form, chronic inflammation with granuloma formation occurs in the mid and deep dermis, often with extension into the subcutis.^{516,521} Numerous fungal elements can usually be seen on the PAS stain.

In white piedra, discrete nodules are found at intervals along the hair shaft. High-power light microscopy shows that the nodules consist of numerous spores. Scanning electron microscopy has shown hyphae perpendicular to the surface that are overlaid by budding arthrospores.⁵³⁵

In black piedra, masses of brown hyphae with ovoid asci containing two to eight single-celled ascospores are present along the hair shaft (see p. 479).⁵³³

Differential diagnosis

Trichosporon organisms in tissue sections should be distinguished from *Candida* species, *Aspergillus*, and *Cryptococcus*; they are easily confused with *Candida*, even though *Trichosporon* hyphae and pseudohyphae are slightly more slender than those of *Candida*. The intensity of staining with Grocott's method is weaker for *Trichosporon* than for *Candida*, but Alcian blue and colloidal iron stains are better for detecting *Trichosporon*, and diluted periodic acid methenamine silver (PAM) particularly enhances the staining of *Trichosporon* compared to *Candida*.⁵³⁶ A peptide nucleic acid probe used for *in situ* hybridization is effective for identifying *Trichosporon* species and provides another means of distinguishing this organism from *Candida*.⁵³⁷

SYSTEMIC MYCOSES

The term 'systemic mycoses' is used here to refer to infections caused by organisms in the following genera: *Blastomyces*, *Coccidioides*, *Paracoccidioides*, *Histoplasma*, and *Cryptococcus*. In most cases, the infection develops initially in the lungs; later, the skin and other organs may be involved. All these organisms except *Cryptococcus neoformans* are dimorphic, growing as mycelia in their natural state and assuming a yeast form in tissues. Cryptococcosis has already been considered with the infections caused by yeasts, and it is not considered further in this section. There are several reports of *Chrysosporium parvum*, a filamentous soil saprophyte, producing pulmonary disease and a localized cutaneous disease.⁵³⁸ It may mimic, histologically, the other diseases included in this section. The dematiaceous fungi have also been excluded from this group.

Patient prognosis in these conditions is influenced by a timely diagnosis and commencement of treatment.⁵³⁹ The diagnostic gold standard, tissue culture, may take days or weeks to complete. Often, tissue is not even submitted for culture because an infective etiology is not considered likely on clinical grounds. *In situ* hybridization using oligonucleotide probes directed against fungal ribosomal RNA is a rapid method of making a specific diagnosis using paraffin-embedded tissue.⁵³⁹

(NORTH AMERICAN) BLASTOMYCOSIS

(North American) blastomycosis, caused by *B. dermatitidis*, occurs on the North American continent and in areas of Africa.^{540,541} Within the United States, most cases are concentrated along the Mississippi, Missouri, and Ohio River basins and the Great Lakes.⁵⁴² It has also been reported in India.⁵⁴³ There are three clinical forms: pulmonary blastomycosis, disseminated blastomycosis, and a primary cutaneous form that results from direct inoculation of organisms into the skin.^{540,544,545} Most cutaneous lesions occur in the course of disseminated disease (secondary cutaneous blastomycosis); in this form, the lesions may be restricted to the lungs, skin, and subcutaneous tissue.^{542,546,547} The rare primary inoculation form may be followed by lymphangitic lesions comparable to those of sporotrichosis.⁵⁴⁰ Distinguishing between primary and secondary cutaneous involvement is sometimes difficult.⁵⁴⁸ The more usual primary lesion is a crusted verrucous nodule, sometimes with central healing and scarring, or an ulcerated plaque.^{546,549} Multiple lesions are sometimes present.⁵⁵⁰ A widespread pustular eruption has been reported;^{551,552} it resembled Sweet's syndrome in one patient.⁵⁵³ The disease is more frequent in adult males. Cases have been reported in children, both immunosuppressed and immunocompetent.^{550,554,555} It shows a predilection for exposed skin, particularly the face.

Treatment of blastomycosis is usually with amphotericin B, fluconazole, or itraconazole.^{542,549,550} Oral itraconazole has been used to treat most recently reported cases of cutaneous disease.

Histopathology⁵⁴⁰

An established verrucous lesion has many histological features in common with chromomycosis and sporotrichosis. There is pseudoepitheliomatous hyperplasia and a polymorphous dermal inflammatory cell infiltrate with scattered giant cells. Microabscesses are characteristic and occur in the dermis and in acanthotic downgrowths of the epidermis (Fig. 25.14). Poorly formed granulomas and suppurative granulomas may be present. In the case resembling Sweet's syndrome (discussed previously), there was a diffuse dermal infiltrate of neutrophils, without epidermal hyperplasia.⁵⁵³ There were scattered histiocytes and giant cells containing budding organisms.⁵⁵³

The thick-walled yeasts measure 7–15 µm in diameter; they are found in the center of the abscesses and in some of the giant cells. A single bud is sometimes present on the surface of the organism (see Fig. 25.14). Giant yeast forms, some greater than 40 µm in diameter, within and surrounding vessels, have been reported in immunosuppressed patients.⁵⁵⁶ If organisms are difficult to find in H&E-stained sections, a PAS or silver methenamine stain will usually demonstrate them. Cases have been misdiagnosed initially as cryptococcosis, but *Cryptococcus neoformans* is usually slightly smaller, and more numerous in the tissue, than *Blastomyces*. Furthermore, it has a mucinous capsule, which is not seen in *Blastomyces*.⁵⁴² *Cryptococcus neoformans* and *C. albicans* do not stain with the Congo red stain, whereas *Blastomyces* does.^{7,8} Errors in diagnosis can be avoided if molecular techniques are used to identify the organism in paraffin-embedded tissue. Antibody probes are now commercially available.⁵³⁹

The primary inoculation form shows less epidermal hyperplasia and a mixed dermal infiltrate containing numerous budding organisms. There are usually no giant cells or granulomas.

Differential diagnosis

The tissue reaction pattern of North American blastomycosis can be seen in a number of other 'deep' fungal infections as well as chromomycosis, protothecosis, and some mycobacterial infections (including *Mycobacterium marinum* infection and tuberculosis verrucosa cutis). A recent case of cutaneous alternariosis showed pseudoepitheliomatous hyperplasia, suppurative dermal inflammation, and nonpigmented yeast forms (although with rare hyphae) that resembled *B. dermatitidis*; however, cultures at two separate inoculation sites grew *Alternaria* species.⁵⁵⁷ There can be a clinical resemblance to halogenodermas, including bromoderma and iododerma, and the latter lesions also have microscopic features of pseudoepitheliomatous hyperplasia and neutrophilic microabscess formation. However, halogenodermas usually do not have significant granulomatous elements, and of course organisms are lacking. *Blastomyces* in tissue sections can be distinguished from other similar fungal infections with yeast forms by their size, thick walls, broad-based buds, lack of endospores, and lack of a capsule.

COCCIDIOIDOMYCOSIS

Infection with *Coccidioides immitis* is most frequently an acute self-limited pulmonary infection resulting from inhalation of dust-borne arthrospores.^{558,559} The disease is endemic in the southwest of the United States, Mexico, and areas of Central and South America.^{560,561} *Coccidioides posadasii* is a recently renamed subspecies of *Coccidioides immitis*.⁵⁶² In less than 1% of cases, but particularly in immunocompromised patients,⁵⁶³ dissemination of the infection occurs. The skin may be involved in disseminated disease, with the cutaneous manifestations taking the form of a verrucous plaque, usually on the face,^{564–567} or subcutaneous abscesses,⁵⁶⁸ pustular lesions,^{568,569} or rarely papules and plaques.^{570,571} Other lesions may be vesicular, nodular, macular, ulcerative, or cystic.⁵⁷² A lupus pernio-like lesion of the nose

Figure 25.14 North American blastomycosis. (A) Typical low-power view of North American blastomycosis, showing pseudoepitheliomatous hyperplasia, intraepidermal neutrophilic microabscesses, and a polymorphous inflammatory infiltrate in the dermis. (B) Yeast forms with thick walls and broad-based budding (arrow). (C) High-power view of *Blastomyces dermatitidis* in tissue. (H&E)

has been reported.⁵⁷³ Although the face is the most common site of occurrence, lesions are also found in the following anatomic sites, in descending order of frequency: lower extremities, shoulders and back, upper extremities, chest, neck, and abdomen.⁵⁷² Disseminated lesions mimicking mycosis fungoides have been reported.⁵⁷⁴ A florid exanthematous eruption may also occur.⁵⁶² Primary cutaneous coccidioidomycosis is extremely rare and follows inoculation of the organisms at sites of minor trauma,⁵⁷⁵⁻⁵⁷⁷ particularly in laboratory⁵⁷⁸ or agricultural workers.⁵⁷⁹ Cases of primary cutaneous coccidioidomycosis were reviewed in 2003.⁵⁷⁶ Rarely, lymphangitic nodules develop, similar to those in sporotrichosis. Erythema nodosum occurs in up to 20% of patients with pulmonary infections, and erythema multiforme and a toxic erythema may also occur.⁵⁶⁸ Hypercalcemia is a rare complication of systemic disease.⁵⁸⁰

DNA hybridization probe tests are now available commercially for the detection of coccidioidomycosis.^{576,581}

The prognosis of primary cutaneous coccidioidomycosis is excellent. Most lesions heal spontaneously without treatment.⁵⁷⁶ Disseminated disease is usually treated with an azole antifungal agent or amphotericin B.⁵⁷⁶ Azoles are contraindicated in pregnancy.⁵⁵⁹

Histopathology

Established lesions show noncaseating granulomas in the upper and mid dermis, with overlying pseudoepitheliomatous hyperplasia of the epidermis.⁵⁶⁴ In a recent large series of cases, pseudoepitheliomatous hyperplasia was seen in approximately one-third of cases. Granulomatous inflammation was a finding common to all cases; other predominating morphologic features included suppurative-granulomatous, lymphoplasmacytic, sarcoid-like, neutrophilic, necrotizing granulomatous, and eosinophilic.⁵⁷² Thick-walled spherules of *Coccidioides immitis*, which usually range from 10 to 80 μm in diameter, are present within the granulomas, often in multinucleate giant cells.⁵⁶⁵ Endospore (sporangiospore) formation is often seen in the largest spherules (sporangia).⁵⁶⁵ The spherules can usually be seen without difficulty in H&E-stained preparations (Fig. 25.15). They are sometimes quite sparse. Mycelial structures have been reported in the lungs, but they are exceedingly rare in cutaneous lesions. They take the form of septate hyphae.⁵⁸² Diagnosis can be made by fine needle aspiration cytology.⁵⁸³

Early lesions and subcutaneous abscesses show numerous neutrophils, with a variable admixture of lymphocytes, histiocytes, and eosinophils.⁵⁷⁹ Eosinophilic abscesses may form.⁵⁶⁶ There are only occasional giant cells. Organisms are usually abundant in these lesions.

Collections of altered red blood cells can rarely mimic the appearances of an endosporulating fungus such as *Coccidioides immitis*. The term 'subcutaneous myospherulosis' has been applied to this artifact (see p. 455).⁵⁸⁴

PARACOCCIDIOIDOMYCOSIS

Paracoccidioidomycosis, also known as South American blastomycosis, is a systemic mycosis confined to Latin America.⁵⁸⁵ There are endemic areas in rural Brazil, Argentina, Colombia, and Venezuela.^{586,587} It is caused by the dimorphic fungus *Paracoccidioides brasiliensis*.⁵⁸⁸ The respiratory tract is the usual portal of entry, from where hematogenous dissemination to other parts of the body occurs.⁵⁸⁹ Disseminated paracoccidioidomycosis with skin lesions has been reported in a patient with AIDS.⁵⁹⁰ A recent case report described disseminated disease in another patient, related to immunosuppression in connection with renal carcinoma.⁵⁹¹ Transcutaneous (primary cutaneous) infection is less common.^{592,593} Oral and mucosal involvement is frequently present in paracoccidioidomycosis, but cutaneous lesions are less common. There are usually several crusted ulcers when the skin is involved.^{594,595} More widespread disease is sometimes present.⁵⁹⁶

Figure 25.15 Coccidioidomycosis. (A) Several large spherules are seen in the dermis. (B) This spherule (sporangium) is releasing its endospores, accompanied by acute inflammation. (H&E)

More than 90% of cases occur in males.⁵⁸⁹ Involvement of the external genitalia is rare; it was found in 6 of 483 patients studied during a 42-year period.⁵⁹⁷

Because of their less toxic side effects, the azole antifungals, particularly itraconazole, have largely replaced amphotericin B for the treatment of skin lesions in the absence of significant systemic involvement.^{589,595} Azoles are fungistatic rather than fungicidal, and relapses may occur some months after the cessation of treatment. Terbinafine and trimethoprim-sulfamethoxazole have also been used.^{598,599} Efforts to develop a vaccine are in progress.⁵⁶¹

Histopathology

Cutaneous lesions often show pseudoepitheliomatous hyperplasia overlying an acute and chronic inflammatory cell infiltrate in the dermis.⁶⁰⁰ Granulomas are usually present, and there may be foci of suppuration. The characteristic feature is the presence of small and large budding yeasts measuring 5–60 μm in diameter.⁶⁰⁰ The buds are distributed on the surface in such a way as to give a 'steering wheel'

appearance.⁶⁰¹ The organisms often have a thick wall with a double-contour appearance.⁵⁹⁸ They can be found in macrophages and foreign body giant cells and lying free in the tissues. They may be overlooked in H&E-stained sections and are best seen with the GMS stain. Like other granulomatous diseases of infective etiology, there is a histological spectrum reflecting the immune response to the organism. The hyperergic pole is characterized by compact epithelioid granulomas and many cells expressing interferon- γ . The anergic pole is represented by parasite-rich lesions and poorly organized granulomas and also by large numbers of cells expressing IL-5 and IL-10.^{586,599} Langerhans cells are present in the dermal/submucosal inflammatory infiltrates, as assessed by langerin (CD207) staining.⁶⁰²

Differential diagnosis

The pseudoepitheliomatous hyperplasia-abscess-granulomatous inflammation image resembles that of a number of other 'deep' fungal infections. Ulcerative lesions, however, are particularly common; this, in addition to the mucocutaneous location of the lesions and occurrence in an endemic area, provides a potential clue to the diagnosis of paracoccidioidomycosis. Forms without multiple buds can mimic *Histoplasma* (when particularly small and intracellular), *Blastomyces*, or capsule-deficient cryptococci. In such circumstances, culture studies may be necessary for definitive diagnosis, although this can be supplemented by serologic testing. Organisms have been detected by PCR technology, and this has been carried out in paraffin-embedded tissues.⁶⁰³ Oral paracoccidioidomycosis can clinically resemble squamous cell carcinoma, but it is amenable to diagnosis through cytological smears stained with Papanicolaou as well as Grocott and PAS stains.⁶⁰⁴ Western blot testing of serum for antibodies to a specific 43-kDa antigen is useful in diagnosing paracoccidioidomycosis and can aid in the differential diagnosis between this disease and tuberculosis.⁶⁰⁵

HISTOPLASMOSIS

Histoplasmosis results from infection with *H. capsulatum*, a dimorphic soil fungus that is endemic in areas of America, Africa, and Asia. In America, it is found in some areas of the southeastern United States and in southern Mexico. The infection is acquired by the inhalation of spores from soil contaminated by bird and bat excreta.⁶⁰⁶ The lung is the most usual primary focus of involvement, except in the African form (see later), and in 99% of cases the pulmonary infection is self-limited and asymptomatic.⁶⁰⁷ Immunosuppression, including AIDS,^{606,608–617} old age, and chronic disease states predispose to disseminated disease.^{618–621} Cutaneous lesions occur in 5% or less of these patients.^{607,619,622} This secondary cutaneous form presents as papules,⁶⁰⁹ ulcerated nodules, cellulitis-like areas, vasculitic lesions, pyoderma gangrenosum-like lesions,⁶²³ tumor-like lesions,⁶²⁴ acneiform lesions,⁶¹⁰ or, rarely, as an erythroderma.^{625,626} Other cutaneous manifestations include plaques (which may be crusted), pustules, erosions, molluscum-like lesions, vegetative lesions, rosacea-like eruptions, keratotic papules with transepidermal elimination, panniculitis, abscesses, and diffuse hyperpigmentation.⁶²⁷ Erythema nodosum is an uncommon manifestation of histoplasmosis.⁶²⁸ Oral involvement has also been reported,⁶²⁹ particularly in patients with AIDS.^{630,631} Rarely, a cutaneous lesion is the only manifestation.⁶³² This primary cutaneous form usually presents as a solitary self-limited ulcerated nodule at the site of fungal inoculation.⁶³³ It has occurred as a laboratory accident.⁶³⁴ Genital histoplasmosis is a rare presentation of primary disease.⁶³⁵ Disseminated cutaneous disease is also rare.⁶³⁶ A cutaneous id-like reaction has been reported in patients undergoing treatment for pulmonary histoplasmosis.⁶³⁷ Rheumatologic manifestations have occurred with histoplasmosis and are believed to result from an inflammatory reaction to the infection rather than as a direct effect

of the organism.⁶³⁸ Erythema, arthritis, and arthralgia have been reported, with knee involvement being the most commonly associated monoarthritis.⁶³⁸

The *African form of histoplasmosis* usually presents with cutaneous granulomas or with skin lesions secondary to underlying osteomyelitis.^{639,640} Disseminated disease can also occur. The causative organism, *H. capsulatum* var. *duboisii*, has much larger yeasts but is otherwise identical in laboratory characteristics to *H. capsulatum*.⁶³⁹

The laboratory diagnosis of histoplasmosis can be made by serological testing, nested PCR assay, positive cultures, or histological visualization of organisms in affected tissue.⁶⁴¹ The histoplasmin skin test is no longer considered useful because a positive reaction does not distinguish a current infection from a past one, and negative reactions often occur in disseminated disease.⁶¹⁹

Treatment varies according to the severity of the disease and the immune status of the patient.⁶²⁹ Oral itraconazole is the treatment of choice for patients who have mild or moderately severe symptoms and also for maintenance therapy.⁶²⁹ Amphotericin B is used for more severe disease and in patients with AIDS.⁶³⁰

Histopathology

Usually, there is a granulomatous infiltrate in the dermis, and sometimes the subcutis,^{642,643} with numerous parasitized macrophages containing small ovoid yeast-like organisms, measuring $2\text{--}3 \times 3\text{--}5 \mu\text{m}$ in diameter. There is often a surrounding clear halo. Langhans giant cells, lymphocytes, and plasma cells are usually present, except in some acute disseminated cases in which parasitized macrophages predominate (Fig. 25.16). Some cases of disseminated disease in HIV-positive patients have shown mild perivascular lymphohistiocytic infiltrates, with intracellular or extracellular organisms demonstrable by GMS,⁶⁴⁴ calcofluor white, or May-Gruenwald Giemsa staining.⁶⁴⁵ The organisms can also be identified on fine needle aspiration cytology.⁶⁴⁶ Extracellular organisms are sometimes found. Transepidermal elimination of macrophages has been reported. Healing lesions show progressive fibrosis. In patients with AIDS, there may be only a sparse inflammatory cell infiltrate. Leukocytoclasia, dermal necrosis, and cutaneous nerve parasitosis may be present in these cases.^{606,614,647}

In the *African form*, the organisms measure $7\text{--}15 \mu\text{m}$ in diameter.⁶⁴⁰ Suppuration is sometimes present,⁶³⁹ but the characteristic tissue reaction is the formation of multinucleate giant cells of classic 'foreign body' type, in the cytoplasm of which are usually 5–12 organisms.

The PAS stain often stains the cell wall of *Histoplasma* poorly.⁷ The broad-spectrum stain, methenamine silver, is always positive. Some organisms are also acid fast.⁷ The use of an immunoperoxidase technique assists in making a specific diagnosis of histoplasmosis on paraffin-embedded material.⁶³⁵

Electron microscopy

The organism has a large eccentric nucleus and a cell wall but no capsule.^{640,648} The fungi are present in phagosomes in the cytoplasm of the macrophages.⁶⁴⁸

Differential diagnosis

Because of their small size and intracellular location, the organisms of histoplasmosis must be distinguished from other 'parasitized histiocyte' diseases, including leishmaniasis, granuloma inguinale, rhinoscleroma, and toxoplasmosis. *Leishmania* organisms have a tendency to line up along the inside cell wall of the macrophage (the 'marquee sign'), are not encapsulated, and have a small basophilic kinetoplast adjacent to the nucleus. *Klebsiella granulomatis*, the organism of granuloma inguinale, is slightly smaller than *H. capsulatum* and shows bipolar staining with the Giemsa method. A capsule appears to be present around these organisms, but it may not be identifiable in routine tissue sections and is best displayed in Epon-embedded thin

Figure 25.16 Histoplasmosis. (A) Innumerable organisms can be seen within macrophages in this biopsy from an immunosuppressed patient. (H&E) (B) There are parasitized macrophages and scant lymphocytes. (H&E) (C) Organisms can be readily identified in this silver preparation. (Grocott stain)

sections. In rhinoscleroma, *K. rhinoscleromatis* organisms reside within particularly large, vacuolated macrophages (Mikulicz cells) and are accompanied by a more prominent plasmacellular infiltrate. PAS and silver stains are also positive in the latter disorder. *Toxoplasma* organisms can sometimes be found in macrophages but also appear as pseudocysts or as groupings within keratinocytes of the epidermis and sweat ducts and within arrector pili muscle. They are weakly positive with PAS but are negative with the GMS stain, and they can also be stained with antibodies specific to *Toxoplasma*. Histoplasmosis and penicilliosis are conditions with similar clinical and laboratory features; differences are subtle, including a greater incidence of tachypnea and neutropenia among histoplasmosis patients.⁶⁴⁹ There are also microscopic similarities because *Penicillium* also parasitizes macrophages. Whereas *Histoplasma* produces small surface buds, *Penicillium* divides by schizogony with the formation of septa within the organism. In addition, hyphal forms can be identified in penicilliosis. Other problematic infections include those due to *Torulopsis glabrata*,⁶⁵⁰ capsule-deficient *Cryptococci*, or lesions containing microforms of *B. dermatitidis*. All of these can display small yeast forms that parasitize macrophages, but each has subtle differences from *Histoplasma*, such as lack of a pseudocapsule; different manner of reproduction; or the presence of other structures, such as larger, thick-walled spores with broad-based buds (*Blastomyces*). *Histoplasma capsulatum* var. *duboisii*, the organism of African histoplasmosis, can mimic *B. dermatitidis* in tissue sections due to its similar size and thick wall, but only the former shows 'double cell' forms (two organisms of similar size connected by a narrow bridge). In addition, unlike *H. capsulatum* var. *duboisii*, *B. dermatitidis* organisms contain multiple nuclei.⁶⁵¹ More specific diagnosis of histoplasmosis can be achieved using immunofluorescence staining, PCR methods, or serologic studies.

INFECTIONS BY DEMATIACEOUS FUNGI

The dematiaceous (pigmented) fungi are a clinically important group.⁶⁵² They are worldwide in distribution, although they are particularly prevalent in tropical and subtropical areas.⁶⁵³ They are found in soil and decaying vegetable matter. The brown pigment of dematiaceous fungi is a melanin, which may be highlighted in tissue sections by the various stains for melanin.⁶⁵⁴ They are capable of producing clinical diseases that range from a mild superficial cutaneous infection to life-threatening visceral disease.⁶⁵⁵ Infection usually results from direct inoculation of infected material into the skin, but inhalation of organisms into the lungs may be the origin in some cases of systemic infection.

Various classifications have been proposed for the infections produced by dematiaceous fungi, with a proliferation of nomenclatures.^{653,656,657} Some of the fungi have been reclassified several times in the past 25 years, resulting in taxonomic confusion. There are two clinicopathological groups, chromomycosis and phaeohyphomycosis,⁶⁵⁷ which represent extremes of a continuum of infections.⁶⁵⁸ Pigmented fungi may also produce mycetomas, which are tumefactive lesions with draining sinuses and the presence of grains in the tissue.⁶⁵⁹ These cases are best considered with the mycetomas caused by other organisms (see p. 707).⁶⁵⁷

Chromomycosis is characterized by localized cutaneous infection and the presence in the tissues of thick-walled septate bodies (sclerotic bodies, muriform cells).⁶⁶⁰ Phaeohyphomycosis^{657,661} (phaeochromomycosis,⁶⁵³ chromohyphomycosis⁶⁶²) is a collective term for a heterogeneous group of opportunistic infections that contain dematiaceous yeast-like cells and hyphae. These infections can be seen following direct implantation of infected material or in immunosuppressed patients, in whom the portal of entry is not always evident.

CHROMOMYCOSIS

Chromomycosis (chromoblastomycosis) is primarily a disease of the tropics and subtropics; it is rare in Europe and North America. It is caused by saprophytic, pigmented fungi commonly isolated from plant debris and soil. Accordingly, it is an occupational hazard in some rural workers.

Chromomycosis starts as a scaly papule, often following superficial trauma, which slowly expands into a verrucous nodule or plaque.^{663–666} In most series, there has been a predilection for the lower legs, but in Australia the upper limbs are most often involved.⁶⁶³ The face, breast, and toenails are rarely infected.^{667–669} It may present with longitudinal melanonychia.⁶⁷⁰ Also rare is presentation as a phagedenic ulcer⁶⁷¹ or dissemination with the formation of generalized cutaneous lesions,⁶⁷² lymphangitic nodules, or hematogenous lesions.^{655,660} Immunosuppression may predispose an individual to these more aggressive lesions.⁶⁷³ Mild lymphedema is often present in the affected limb.⁶⁷⁴

The eight species that have been incriminated include *Fonsecaea pedrosoi*^{675,676} (*Phialophora pedrosoi*), *Phialophora compacta* (*Fonsecaea compacta*),^{677,678} *Phialophora verrucosa*, *Cladosporium carrionii*,⁶⁷⁹ *Aureobasidium pullulans*,⁶⁸⁰ and, rarely, *Rhinocladiella aquaspersa* (*Acrotheca aquaspersa*).⁶⁵⁵ Although it is a well-recognized cause of phaeohyphomycosis, *Exophiala spinifera* has been documented as a cause of chromomycosis in only several cases.⁶⁸¹ The eighth species to cause human disease, *Chaetomium funicola*, was reported in 2007 from western Panama as a single case report.⁶⁸² It is an opportunistic fungus found in soil. Other species recently described in chromomycosis include *Fonsecaea nubica*,⁶⁸³ *Fonsecaea monophora*,^{684–687} and *Phialophora richardsiae*.⁶⁸⁸ Although sometimes cited as a cause,⁶⁵³ *Wangiella dermatitidis* (*Phialophora dermatitidis*) is now no longer considered to be involved.⁶⁸⁹ *Fonsecaea pedrosoi* is the most commonly isolated organism, except in Australia, where *Cladosporium carrionii* is usually responsible.

Squamous cell carcinomas may develop in lesions of chromomycosis; they often arise in lesions of long duration, in patients who are not necessarily immunosuppressed,^{690,691} and may run an aggressive course.^{692,693} Malignant melanoma may also supervene.⁶⁹⁴

The treatment of choice for small lesions is surgery; they may be misdiagnosed clinically as skin cancers and treated accordingly. Treatment of lesions by cryosurgery with liquid nitrogen⁶⁹⁵ or with the carbon dioxide laser⁶⁹⁶ are other treatment options. Itraconazole alone or with cryotherapy has been used.⁶⁷⁴ It may also be used with flucytosine. Intermittent, pulse itraconazole is a further option.⁶⁹⁷ Terbinafine and fluconazole are other treatment options. Amphotericin B is now used for systemic or disseminated cutaneous disease.⁶⁶⁸ Topical heat applications can supplement other therapies.

Histopathology^{657,660}

The appearances are similar to sporotrichosis, with hyperkeratosis, pseudoepitheliomatous hyperplasia, and granulomas in the upper and mid dermis. The granulomas are mostly of tuberculoid type, although a few suppurative granulomas are usually present. Intraepidermal microabscesses are often present, but these are not as numerous as in sporotrichosis. There is a background infiltrate of chronic inflammatory cells, and sometimes a few eosinophils, in the upper dermis. Round, thick-walled, golden brown cells (sclerotic bodies, muriform cells, medlar bodies), 5–12 µm in diameter, can be seen in giant cells and lying free in the intraepidermal microabscesses (Fig. 25.17).⁶⁹⁸ These sclerotic bodies are thought to be an intermediate vegetative form, arrested between yeast and hyphal morphology.⁶⁵⁷ They are usually seen readily in H&E preparations and particularly in sections stained with hematoxylin alone. Because of their natural pigmentation, these bodies are particularly well seen in unstained and destained sections.⁶⁹⁹ Stains such as PAS and silver

Figure 25.17 Chromomycosis. (A) There is marked pseudoepitheliomatous hyperplasia. (B) A brown spore is present in the cytoplasm of a macrophage. This granuloma is more typical. (C) High-power view of a septate body. (H&E)

methenamine often obscure the natural pigmentation of the fungal cells, and this can result in misdiagnosis of the type of fungus. Ziehl–Neelsen (ZN) and Wade–Fite stains can also be used to demonstrate these bodies.⁷⁰⁰ The fungal cells have a diversity of internal ultrastructure.^{701,702} Hyphae have been reported in the stratum corneum in an otherwise typical case of chromomycosis^{703,704} and in the dermis and subcutaneous tissue of another case.⁷⁰⁵ A case due to *Rhinocladiella aquaspersa* showed hyphae in tissue sections rather than muriform cells.⁷⁰⁶

The pseudoepitheliomatous hyperplasia is probably the mechanism by which the transepithelial elimination of the fungal bodies and inflammatory debris takes place.⁷⁰⁷ There is progressive dermal fibrosis, and this is quite prominent in treated lesions.⁷⁰⁸

A rare and unusual response is the effacement of the dermis by a spindle cell, a fibrohistiocytic response with some cells demonstrating nuclear atypia and scattered mitotic figures.⁷⁰⁹ Pigmented spores can be seen in the lesional giant cells. The fibrous response is thought to result from the high levels of pyridinoline produced by the fungi.⁷⁰⁹

In sporotrichosis, foci of suppuration and suppurative granulomas are more obvious than in chromomycosis. Furthermore, the absence of organisms on a single H&E section favors sporotrichosis because septate bodies are almost invariably found in a single section of chromomycosis.

Antigens of *F. pedrosoi* have been detected by immunohistochemical techniques in lesional skin, chiefly in macrophages but also in Langerhans cells and factor XIIIa dendrocytes.⁷¹⁰

PHAEOPHYCOMYCOSIS

The term 'phaeophycomycosis' is used for a diverse group of dematiaceous fungal infections⁶⁵⁷ whose hallmark is the presence in tissues of pigmented hyphae. Four clinical categories are recognized: superficial (black piedra and tinea nigra), cutaneous or corneal, subcutaneous, and visceral (systemic).⁶⁵⁷ Some overlap exists between the cutaneous and subcutaneous forms. Thirty-six different species of fungi were listed in one review article as being involved in the etiology of phaeophycomycoses.⁶⁶⁰ The most commonly isolated fungi in cutaneous and subcutaneous lesions are *Exophiala jeanselmei* (which some mycologists now consider to be identical with *Phialophora gougerotii*)^{655,657,711–714} and *Wangiella dermatitidis*.⁶⁵⁷ These fungi may also be isolated in the systemic forms involving the brain or other viscera. Cutaneous and/or subcutaneous lesions have also resulted from infection with *E. spinifera*,^{715,716} *E. dermatitidis*,⁷¹⁷ *E. oligosperma*,⁷¹⁸ *E. xenobiotica*,⁷¹⁹ *E. salmonis*,⁷²⁰ *E. equina*,⁷²¹ *Curvularia pallescens*,⁷²² *Curvularia lunata*,^{723,724} *Nattrassia magniferae*,⁷²³ *Fonsecaea* spp.,^{723,725} *Hormonema dematioides*,⁷²⁶ *Bipolaris spicifera*,^{727,728} *Phoma* sp.,^{729,730} *Geniculosporium* sp.,⁷³¹ *Colletotrichum* spp.,⁷³² *Aureobasidium pullulans*,⁷³³ *Cladophialophora bantiana*,^{734–737} *Cladophialophora boppii*,⁷³⁸ *Cladosporium cladosporioides*,⁷³⁹ *Veronaea botryosa*,^{740,741} *Wallemia sebi*,⁷⁴² *Phaeoacremonium aleophilum*,⁷⁴³ *Phaeoacremonium rubrigenum*,⁷⁴⁴ *Alternaria alternata*,⁷⁴⁵ *Alternaria malorum*,⁷⁴⁶ *Alternaria infectoria*,⁷⁴⁷ *Chaetomium brasiliense*,⁷⁴⁸ *Corynespora cassiicola*,⁷⁴⁹ *Ochroconis tshawytschae*,⁷⁵⁰ *Paraconiothyrium cyclothyrioides*,⁷⁵¹ *Pyrenochaeta romeroi*,⁷⁵² *Rhinocladiella basitona*,⁷⁵³ *Phialophora verrucosa*,⁷⁵⁴ and *Phialophora richardsiae*.⁷⁵⁵ Other fungi involved in systemic infection include *Cladosporium trichoides*⁶⁵³ and *Exserohilum* sp.^{655,727,756–758} Patients with systemic infections are usually immunosuppressed,^{724,727,756,759} but disseminated disease has been reported in immunocompetent patients.^{745,760}

Cutaneous lesions may be nodular, cystic, or verrucous.⁷⁶¹ They are usually solitary. Some patients are immunocompromised;^{537,762–764} in others, the lesion follows a penetrating injury with implantation of a wood splinter or other vegetable matter.^{765,766} The most common lesion is a subcutaneous cyst on the distal parts of the extremities.⁷⁶⁷ Sporotrichoid lesions have been reported.⁷⁶⁸

Figure 25.18 Phaeophycomycosis. (A) A small wood splinter is present in the 'cyst'. (H&E) (B) The fungal elements are present in the inflammatory lining of the cavity. (PAS–tartrazine)

Treatment of cutaneous phaeophycomycosis includes surgical excision, oral itraconazole, terbinafine, and amphotericin B for disseminated cases.^{736,767,769}

Histopathology^{765,770–772}

The characteristic lesion is a circumscribed cyst or chronic abscess situated in the subcutis or lower dermis (Fig. 25.18).⁷⁷³ The wall is composed of dense fibrous tissue with a chronic granulomatous reaction adjacent to the cavity. The wall also contains chronic inflammatory cells and scattered giant cells. There is a central cystic space containing necrotic debris with some admixed neutrophils. A wood splinter or similar foreign body is sometimes present. Brown filamentous hyphae and yeast-like structures may be present in the wall, in giant cells, or in the debris. Sometimes the fungal elements can be seen in relation to the implanted foreign material.^{774,775}

In some cases, the lesions resemble those of cutaneous chromomycosis.⁶⁵⁶ They may present simply as ulcerated, partly necrotic granulomas containing the characteristic pigmented hyphae.⁷⁷⁶

Differential diagnosis

More lightly stained organisms could be confused with other opportunistic fungi, such as the organisms of hyalohyphomycosis. However,

the latter have much thinner walls, and close inspection using the high dry or oil objectives usually shows some degree of pigment in organisms of phaeohyphomycosis. Although there is a resemblance to the pigmented fungal organisms causing mycetoma, grain formation is not a characteristic of phaeohyphomycosis. The other brown-staining fungal organisms are those causing chromomycosis, but in tissue sections these consist of spherical bodies that reproduce by internal septation. Also, they are often found in the setting of a blastomycosis-like tissue reaction, with pseudoepitheliomatous hyperplasia and transepidermal elimination of the fungal elements. However, the editor has seen a blastomycosis-like tissue reaction pattern in a case of phaeohyphomycosis due to *Cladophialophora bantiana*.

SPOROTRICHOSIS

Sporotrichosis is an uncommon fungal infection of worldwide distribution, caused by the dimorphic fungus *S. schenckii*.⁷⁷⁷ It is endemic in Mexico and Central America, where infection rates in rural areas may approach one case per 1000 of the population.^{778,779} Infection usually results from percutaneous implantation of infected vegetable matter, particularly wood splinters, or from injury by rose thorns or contamination of even minor skin wounds by infected hay and sphagnum moss.⁷⁸⁰⁻⁷⁸⁴ Infection has also been acquired from animals⁷⁸⁵⁻⁷⁸⁷ and in the laboratory. Most cases occur in adults, but children are sometimes affected.^{788,789}

There are three main clinical presentations of sporotrichosis: lymphangitic, localized (fixed), and disseminated.⁷⁹⁰ The *lymphangitic form* (lymphocutaneous or sporotrichoid form) begins as a single nodule or ulcer and is followed by the development of subcutaneous nodules along the course of the local lymphatics. The initial and secondary nodules may ulcerate. This type accounts for 75% or more of all cases of sporotrichosis in many reports, but it is much less common in Australia and South Africa.^{781,791-793} The *localized form* (fixed form) presents as an ulcerated nodule or verrucous plaque that measures 1–5 cm or more in diameter.^{794,795} It has been suggested that this form is more likely to develop in patients previously sensitized to *S. schenckii*, but this does not explain why lesions in children,⁷⁹⁶⁻⁷⁹⁹ and those on the face,^{800,801} are often of this type. The subtype of the organism and the temperature sensitivity of the particular strain of organism involved have also been suggested as influencing the clinical type of lesion.^{802,803} More than 30 subtypes of *S. schenckii* have been identified, and the various subtypes show strong geographic specificity.⁷⁷⁸ The upper limbs are the most common site of involvement in both types of sporotrichosis. Unusual sites of involvement include the penis, pubic region, and oral mucous membrane.⁸⁰⁴ Spontaneous disappearance of lesions⁸⁰⁵ and exogenous second infections⁸⁰⁶ have also been documented.

Rarely, cutaneous lesions are erysipeloid⁸⁰⁷ or generalized,⁸⁰⁸ with the latter form usually occurring in association with visceral involvement.⁸⁰⁹⁻⁸¹¹ Such lesions may clinically mimic pyoderma gangrenosum.⁸¹²⁻⁸¹⁴ Visceral involvement (the *disseminated form*) may also occur without associated skin lesions.⁸¹⁵ The lungs, bones, joints, and meninges are favored sites of extracutaneous involvement.⁸¹⁵⁻⁸¹⁸ Disturbances in cell-mediated immunity (including AIDS),^{819,820} cancer,⁸¹⁶ and sarcoidosis⁸²¹ have been present in some, but not all,⁸²² patients with disseminated sporotrichosis.⁸²³ Co-infection with leishmaniasis has been reported.⁸²⁴

Potassium iodide was the treatment of choice for many years. It is still used in some countries with endemic disease.^{788,804,825} Itraconazole has replaced it in some areas of the world.⁷⁷⁹ An itraconazole pulse regimen is a safe and effective alternative therapy for sporotrichosis.⁸²⁶ Other azole, polyene, or allylamine antifungal agents have been used.⁷⁸⁹ Heat therapy can be used alone or with antifungal agents. In Australia, where the localized form is the predominant type, excision of the

Figure 25.19 Sporotrichosis. This localized lesion is characterized by pseudoepitheliomatous hyperplasia of the epidermis and suppurative granulomas in the upper dermis. (H&E)

lesion is often carried out because the lesions are frequently misdiagnosed as squamous cell carcinomas.

Histopathology^{791,827}

In the localized form, there is usually prominent pseudoepitheliomatous hyperplasia with some overlying hyperkeratosis and focal parakeratosis (Fig. 25.19). Several types of granulomas are found within the dermis, including tuberculoid, histiocytic, and suppurative granulomas. Liquefaction or caseous necrosis were found in a high percentage of cases in one study.⁸²⁸ Multinucleate giant cells may be present at the periphery of the granulomas, and some of these are of foreign body type. Intraepidermal microabscesses are not uncommon.

In the lymphangitic form, the inflammatory nodules are situated in the lower dermis and there are usually no epidermal changes. There is often a more diffuse inflammatory infiltrate, and the granulomas are mostly of the suppurative type. Coalescence of abscesses may occur.

The traditional view has always been that fungal elements are infrequently demonstrated in human cases of sporotrichosis. For example, in a recent study of 119 specimens, organisms were not found in 64.7% of them.⁸²⁸ However, in our study of 39 cases, only 2 of which were of lymphangitic type, fungal elements were found in all cases. This was achieved by examining multiple serial sections, some stained with H&E and others with PAS.⁸²⁷

The sporothrix may be present in the tissues as yeast-like forms 2–8 µm in diameter, as elongated cells ('cigar bodies') 2–4 × 4–10 µm, or as hyphae.⁸²⁹ Hyphae are particularly rare.^{829,830} A characteristic finding is the 'sporothrix asteroid': this is a yeast form (blastospore) surrounded by an intensely eosinophilic, hyaline material, the ray-like processes of which extend for a short distance from the core (Fig. 25.20). The hyaline material stains faintly with PAS. This material represents deposits of immune complexes on the surface of the fungal cell. The central yeast stains with anti-*Sporothrix* antibodies, but the surrounding eosinophilic, ray-like processes do not.⁸³¹ Asteroids are found only in the center of suppurative granulomas and suppurative foci. In our experience, each such focus will contain an asteroid, if examined by serial sections.⁸³¹ Asteroids can also be found in fresh pus removed from lesional skin by compression.⁸³² Spores can usually be demonstrated using a silver methenamine or PAS stain. Prior digestion with malt diastase has been suggested as a method to enhance recognition of spores in PAS preparations.⁸³³ Numerous spores are sometimes present,⁸³⁴ particularly if the lesion has been injected with steroids because of a mistaken clinical diagnosis (Fig. 25.21).⁸³⁵

Figure 25.20 Sporotrichosis. (A), (B) A *Sporothrix* asteroid is present in a suppurative granuloma. (H&E)

Figure 25.21 Sporotrichosis. Numerous fungal elements are present. This lesion was injected with corticosteroids because of a mistaken clinical diagnosis of granuloma annulare. (H&E)

Differential diagnosis

The most common problem encountered in the diagnosis of sporotrichosis is the inability to find organisms in tissue sections despite careful search. Lesions with similar clinical and microscopic appearances can also occur due to cutaneous tuberculosis⁸³⁶ or atypical mycobacterial infection, and those organisms can be similarly difficult to identify. Other organisms associated with a blastomycosis-like tissue reaction pattern can potentially be confused with *S. schenckii*, especially if found as isolated yeast forms. The histopathologic features of sporotrichosis can closely resemble those of American tegumentary leishmaniasis, a problem compounded by the difficulty of finding organisms in some cases. In comparing the two diseases, it was found that ‘macrophage concentration’ (a feature of leishmaniasis) and ‘suppurative granuloma’ (a feature of sporotrichosis) had the highest reliability in selecting the correct diagnosis, with an accuracy of 92%.⁸³⁷ The changes in lymphatic nodules of sporotrichosis are similar to the ‘stellate’ abscesses seen in lymphogranuloma venereum, tularemia, and cat-scratch disease. Resolution of these issues requires culture study, direct immunofluorescence staining for *S. schenckii* (if available), or serologic testing. In one study of experimental sporotrichosis in mice, culture and antibody testing on blood samples were actually of greater diagnostic value than the nested PCR method.⁸³⁸

TINEA NIGRA

Tinea nigra is a rare asymptomatic mycosis of the stratum corneum caused by a dematiaceous fungus, *Phaeoanellomyces* (*Exophiala*) *werneckii*.^{839,840} It presents as a slowly enlarging, brown to black macule, or large patch, involving the palms^{841–845} or palmar surfaces of the fingers⁸⁴⁶ and, less commonly, the plantar^{847,848} or lateral surfaces of the feet.⁸⁴⁹ Lesions are sometimes bilateral.⁸⁴⁷ Tinea nigra is more common in tropical areas. Children and adolescents may be involved.⁸⁴⁵ Clinically, it may mimic various melanocytic lesions.⁸⁴⁹

Topical antifungals from the imidazole family are the most effective treatment.⁸⁴⁴

Histopathology⁸⁴⁹

The stratum corneum may be slightly more compact than usual. Numerous brown hyphae are present in its superficial layers and are easily seen in H&E-stained sections. Spores may also be shown by the PAS stain. There is usually no inflammatory reaction (Fig. 25.22).

Dermoscopic examination shows fine wispy light brown strands of uniform color, forming a reticulated patch without following the furrows and ridges characteristic of palms and soles.⁸⁵⁰ This is in contrast to melanocytic lesions in the same locations, which show a parallel ridge pattern with pigment on the ridges (acral melanomas) or a parallel furrow pattern with pigment on the furrows (acral nevi).⁸⁵⁰

ALTERNARIOSIS

Members of the genus *Alternaria* are plant pathogens. They are a rare cause of infection in humans, affecting both healthy^{851,852} and, more usually, immunodeficient individuals.^{853–859} The usual species, *A. alternata*, produces chronic, (sometimes) crusted nodules, pustules, or ulcers localized to an exposed area such as the face, forearms, hands, and knees.^{860–865} Sometimes, there are large ulcerated plaques intermingled with pustules.^{866,867} Subcutaneous nodules on the chest in association with *A. dianthicola*,⁸⁵³ and a nodule on the nasal septum caused by *A. chartarum*,⁸⁶⁸ have been reported. *Alternaria chlamydospora*, *A. tenuissima*, and *A. infectoria* are other extremely rare human pathogens.^{869–871} The rationale for including this group with the dematiaceous fungi, in the absence of pigmented tissue elements, is the

Figure 25.22 Tinea nigra. Numerous brown hyphae are present in the superficial layers of the compact stratum corneum. (H&E)

formation of gray to black colonies on culture. Alternariosis is considered by some as a phaeohyphomycosis.⁸⁷²

Treatment is usually with antifungal agents such as oral itraconazole or fluconazole,⁸⁷³ but there is one report of thermotherapy being successful for a subcutaneous infection.⁸⁷⁴

Histopathology^{860,875}

Usually, there are noncaseating granulomas of tuberculoid, suppurative, or sarcoidal type and also chronic inflammation in the dermis, often with a few microabscesses. Sometimes the microabscesses are prominent.⁸⁷⁶ Necrotizing folliculitis is sometimes present.⁸⁷⁷ Epidermal involvement may accompany the dermal inflammation or occur as the only manifestation. It is characterized by intraepidermal abscesses and often a thick scale crust containing neutrophils. Pseudoepitheliomatous hyperplasia is present in nearly half of the cases. Septate hyphae and spores, variably pigmented,⁸⁷⁸ can be seen in the dermis and epidermis.⁸⁷⁹ As noted previously, examples with a predominance of round to ovoid forms and unipolar budding can resemble *B. dermatitidis*; however, rare hyphal forms can often be identified in such cases, and the diagnosis of alternariosis can be confirmed by culture studies.⁸⁵⁷ PCR-based techniques can be used to confirm the diagnosis.⁸⁵²

The organisms often show degenerative changes on electron microscopic examination.⁸⁸⁰

MYCETOMA AND MORPHOLOGICALLY SIMILAR CONDITIONS

On a strict etiological basis, only the eumycetic mycetomas (mycetomas caused by true fungi) should be included in this chapter. As will be seen from the discussions that follow, a similar tissue reaction can be produced by filamentous bacteria of the order Actinomycetales (actinomycetic mycetoma) and certain other bacteria (botryomycosis).⁸⁸¹ This is the rationale for the inclusion here of actinomycosis, nocardiosis, and botryomycosis.

MYCETOMA

Mycetoma is an uncommon chronic infective disease of the skin and subcutaneous tissues that is characterized by the triad of tumefaction,

draining sinuses, and the presence in the exudate of colonial grains.^{882–885} The sinuses do not develop until relatively late in the course of the disease, discharging grains that are aggregates of the causal organism embedded in a matrix substance.^{886,887} There are two main etiological groups of mycetoma: actinomycetic mycetomas, which are caused by aerobic filamentous bacteria of the order Actinomycetales, and eumycetic (maduromycotic) mycetomas caused by a number of species of true fungi.^{888–890} The therapy of these two groups is quite different.⁸⁹¹ Similar clinical lesions can be produced by traditional bacteria (botryomycosis) and rarely by dermatophytes.^{883,892–894} Dermatophyte-induced mycetoma must be distinguished from a kerion (see p. 686). The term pseudomycetoma is used for deep infections by dermatophytes in which draining sinuses are absent.^{34,35,895}

Mycetoma is predominantly a disease of tropical countries, particularly West Africa, areas of India, and Central and South America.⁸⁹⁶ There are only sporadic reports of cases in the United States,⁸⁹⁷ Canada, Europe (including the United Kingdom),⁸⁹⁸ and Australia.⁸⁹⁹ Different species predominate in different countries.^{896–900} For example, in Mexico, up to 85% of cases are caused by *Nocardia brasiliensis*,⁹⁰¹ whereas in Yemen, eumycetomas caused by *Madurella mycetomatis* predominate and lesions caused by *Nocardia* are uncommon.⁹⁰² Rural workers, particularly males, are most commonly infected. More than 70% of infections occur on the feet (Madura foot), with the hand the next most common site of involvement. Perianal lesions have also been reported.⁹⁰³ Isolated cases of eumycetoma have been reported in recipients of organ transplants.⁹⁰⁴

Repeated minor trauma or penetrating injury provides a portal of entry for the organism, which then produces a slowly progressive subcutaneous nodule after an incubation period of several weeks or months.^{896,905,906} Sometimes there is no history of trauma.⁹⁰⁷ Sinuses develop after 6–12 months. Extension to involve the underlying fascia, muscle, and bone is common. Rarely, there is lymphatic dissemination to regional lymph nodes.⁸⁸⁷ No unequivocal cases of visceral dissemination have been reported.⁹⁰⁸ Actinomycetic mycetomas often expand faster, are more invasive, and have more sinuses than eumycetic variants.⁸⁹⁶ Helical computed tomography has been used to evaluate the invasion of actinomycetoma.⁹⁰⁹

Macroscopic features of the grains

The grains discharged from the sinuses vary in size, color, and consistency – features that can be used for rapid provisional identification of the etiological agent.⁸⁹⁶ More than 30 species have been identified as causes of mycetoma, and the grains of many of these have overlapping morphological features. Accordingly, culture is required for accurate identification of the causal agent.

The size of the grains varies from microscopic to 1 or 2 mm in diameter. Large grains are seen with madurellae (particularly *Madurella mycetomatis*) and with *Actinomadurella madurae* and *A. pelletieri*, whereas the granules of *Nocardia brasiliensis*, *N. cavae*, and *N. asteroides* are small. Discharging grains are not always seen. They were not seen in a mycetoma caused by *Scytalidium dimidiatum*, an extremely rare cause of this condition.⁹¹⁰

The colors of the grains of the most common species are shown in **Table 25.1**. Dark (black) grain mycetomas are found only among the eumycetic mycetomas.⁹¹¹ The pigment is a melanoprotein or related substance.⁹¹² The consistency of most grains is soft, but those of *Streptomyces somaliensis* and *Madurella mycetomatis* can be quite hard.⁸⁸⁷ *Cladophialophora bantiana*, usually associated with cerebral infections, has been responsible for nine cutaneous cases; they were reviewed in 2005.⁹¹³ It has black grains. Newly reported or unusual organisms in the eumycetoma category include *Neoscytalidium dimidiatum* (brownish grains),⁹¹⁴ *Phaeoacremonium parasiticum* (formerly *Phialophora parasitica* – previously reported but producing a white-yellow grain),⁹¹⁵ *Pseudozyma aphidis* (with co-infection by *Nocardia*

The usual treatment of eumycetoma is based on ketoconazole or itraconazole.^{907,920} Prior surgical debridement is sometimes carried out. Small lesions may be excised.⁹⁰⁵ Voriconazole has also been used successfully.⁹²⁰ Sometimes amputation is required despite therapy.⁸⁹⁰

Histopathology^{882,887}

The characteristic grains are found in the center of zones of suppuration and in suppurative granulomas in the subcutis (Fig. 25.23). Neutrophils sometimes invade the grains. Surrounding the areas of suppuration, there may be a palisade of histiocytes, beyond which is a mixed inflammatory infiltrate and progressive fibrosis. A few multinucleate giant cells are usually present. An eosinophilic fringe, resembling the Splendore–Hoeppli phenomenon found around some parasites, is sometimes present around the grains.

Several reviews have discussed the morphology of the grains on light microscopy.^{887,896} Some of these features are highlighted in Table 25.2.^{921–923} Note that the granules in pale-grain eumycetomas are not morphologically distinctive and there is overlap between the various species.

The large segmented mycelial filaments (2–4 μm in diameter, with club-shaped hyphal swellings and chlamydospores) that characterize the fungi that cause eumycetomas (Fig. 25.24) contrast with the gram-positive thin filaments (1 μm or less in diameter) of the organisms that cause actinomycetomas.^{882,899}

Differential diagnosis

The clinical presentation, combined with abscess formation, draining sinuses, and grains, leads to a diagnosis of mycetoma. Microscopic examination can help distinguish the grains of botryomycosis (which contain conventional bacteria – usually gram-positive cocci) from those caused by filamentous bacteria and fungi. Similarly, morphology and differential staining can help separate actinomycetoma caused by filamentous, gram-positive bacteria from eumycetoma caused by fungi that form true hyphae. Identification of the particular species involved would then require culture studies.

NOCARDIOSIS

Nocardiae are usually gram-positive, partially acid-fast bacteria that are native to soil and decaying vegetable matter.^{924,925} The common pathogenic species are *N. asteroides*,⁹²⁶ *N. brasiliensis*,^{927,928} and *N. caviae*.^{929,930} *Nocardia farcinica*, now acknowledged to be a species distinct from *N. asteroides*, can produce severe systemic infections with subcutaneous abscesses. Other species are rarely implicated.^{931–935}

Figure 25.23 (A) Mycetoma. (B) An irregularly shaped grain is present in the center of a zone of suppuration. (H&E)

The majority of cases of nocardiosis are septicemic infections, usually of pulmonary origin, in immunocompromised patients.^{926,936–938} Cutaneous lesions develop in approximately 10% or more of hematogenous infections.^{939,940} Primary cutaneous involvement can be of three different types: mycetoma, lymphocutaneous infection, and superficial cutaneous infections, which may take the form of an abscess, an ulcer, or cellulitis.^{928,941–947} The lymphocutaneous (sporotrichoid,⁹⁴⁸ chancriform) infection,⁹⁴⁹ which includes a cervicofacial variant in children,⁹⁵⁰ resembles sporotrichosis in having subcutaneous nodules along the course of the superficial lymphatics.^{951–955} A history of trauma is often present in primary cutaneous lesions.^{926,952–960}

Whereas *N. asteroides* is responsible for most pulmonary, cerebral, and septicemic infections, *N. brasiliensis* is the most common nocardial pathogen in the skin.^{924,961–963} There have been many exceptions to this generalization.^{944,964–968} Both species of *Nocardia* have been isolated from a mycetoma on the forehead,⁹⁶⁹ and both *N. asteroides* and *S.*

Table 25.2 Morphology of the grains (granules) in mycetomas**Eumycetomas**

Madurella mycetomatis: Large granules (up to 5 mm or more) with interlacing hyphae embedded in interstitial brownish matrix; hyphae at periphery arranged radially with numerous chlamydospores

Petricalidium boydii: Eosinophilic, lighter in the center; numerous vesicles or swollen hyphae; peripheral eosinophilic fringe; other pale eumycetomas have a minimal fringe and contain a dense mass of intermeshing hyphae

Actinomycetomas

Actinomadura madurae: Large (1–5 mm and larger) and multilobulate; peripheral basophilia and central eosinophilia or pale staining; filaments grow from the peripheral zone

Streptomyces somaliensis: Large (0.5–2 mm or more) with dense thin filaments; often stains homogeneously; transverse fracture lines

Nocardia brasiliensis: Small grains (approximately 1 mm); central purple zone; loose clumps of filaments; gram-positive delicate branching filaments breaking up into bacillary and coccid forms; gram-negative amorphous matrix (Brown and Benn method)

Figure 25.24 Eumycetoma. The fungal elements comprising this grain are easily seen. (PAS stain)

schenkii have been isolated from a mycetoma of the forefoot.⁹⁷⁰ A concurrent double infection with *E. spinifera* and *N. asteroides*, the latter producing lymphocutaneous nocardiosis, has been reported.⁹⁷¹ Other species of *Nocardia* reported to cause mycetoma include *N. nova* (in a lepromatous leprosy patient),⁹⁷² *N. harenae*,⁹⁷³ *N. yamanashiensis*,⁹⁷⁴ *N. takedensis*,⁹⁷⁵ and *N. pseudobrasiliensis*.⁹⁷⁶

The treatment of choice for *Nocardia* is trimethoprim-sulfamethoxazole.^{903,937,977} Amoxicillin-clavulanate and dapsone were successful in two individual cases.^{901,933} Sometimes an intravenous cocktail of antibiotics is required, including amikacin and imipenem.^{934,935}

Histopathology

There is usually a dense infiltrate of neutrophils in the deep dermis and subcutis, with frank abscess formation.⁹⁷⁸ In chronic lesions, there is a thin fibrous capsule and many chronic inflammatory cells. Necrosis, hemorrhage, and ulceration may all be present at times.⁹⁶⁵

The organisms are not readily visible in H&E-stained sections. Special stains show them to be fine, branched filaments that are gram positive, usually weakly acid fast, and that stain with the silver methenamine method.⁹⁷⁹ Colonial grains are uncommon in cutaneous lesions other than mycetomas.⁹⁸⁰

Differential diagnosis

The differential diagnosis with regard to mycetoma due to *Nocardia* is similar to that for actinomycosis. *Nocardia* infection unassociated with grain formation should be differentiated from other infections due to filamentous bacteria. Compared to *Actinomyces*, *Nocardia* organisms are shorter and have a greater tendency to fragment, sometimes even forming bacillary structures. Although it is generally thought that *Nocardia* species are acid-fast and *Actinomyces* species are not, the latter can be acid-fast under certain conditions, notably with the Putt modification of the Ziehl-Neelsen stain,⁹⁸¹ whereas *Nocardia* is only weakly acid-fast with the traditional Ziehl-Neelsen method. It is also doubtful that methenamine silver stains are truly helpful in distinguishing small bacillary fragments of *Nocardia* from other acid-fast bacilli, as has been suggested in the past, because both *M. tuberculosis* and *M. leprae* are stainable with methenamine silver stains under varying conditions.^{982–984} Therefore, specific *in situ* hybridization methods or culture studies may be necessary in some cases.

ACTINOMYCOSIS

Actinomycosis is a chronic, sometimes fatal, infection that may involve any part of the body.^{985–989} Its cutaneous manifestations include fluctuant swellings, which may progress to draining sinuses in the cervicofacial, thoracic,⁹⁹⁰ or abdominal region.⁹⁹¹ In the latter site, there is often underlying visceral involvement or a history of previous surgery in the region. Perineal and perianal infections may also occur.^{903,992} Surgical procedures at other sites may result in primary cutaneous lesions, particularly in the presence of diabetes mellitus or immunosuppression.^{977,993} Multiple subcutaneous abscesses may result from hematogenous dissemination of a visceral infection.⁹⁹⁴

The causal organism is *Actinomyces israelii*, a filamentous bacterium that is isolated with difficulty by anaerobic culture. It forms tiny, soft granules that may be detected in the pus ('sulfur granules'). *Actinomyces israelii* is a normal inhabitant of the oral cavity. Similar lesions can be caused by other actinomycetes, including species of *Streptomyces* and *Actinomadura*.^{995,996}

There are few reports in the dermatological literature on the treatment of actinomycosis. One case was successfully treated with a combination of amoxicillin and minocycline.⁹⁹³ Long-term, high-dose penicillin is the treatment of choice.⁹⁸⁹

Histopathology⁹⁸⁵

The usual cutaneous lesion is a subcutaneous abscess. There are often several foci, which are separated by areas of granulation tissue in which foamy macrophages are present.⁹⁸⁵ There is an outer zone of granulation and fibrous tissue at the periphery of the abscess cavities, and this contains lymphocytes, plasma cells, and some macrophages.

One or more colonial granules are present in the pus. These average approximately 300 µm in diameter but may range up to 1 or 2 mm.⁹⁸⁵ At the periphery of the granules, club-shaped bodies radiate in a parallel manner from the border. The clubs and matrix of the granules are gram negative. The granules are composed of numerous slender beaded filaments that tend to be crowded at the periphery of the granules.⁹⁸⁵ They are gram positive but typically not acid fast.⁹⁸¹ They are usually PAS positive and stain gray or black with the silver methenamine stain. Free organisms are infrequently seen.

Differential diagnosis

Microscopically, actinomycosis should be distinguished from the other infections that produce grains in tissues. Botryomycosis is associated with conventional, nonfilamentous bacteria, both gram positive and

gram negative (frequently *Staphylococcus aureus*). These can be well demonstrated with Giemsa as well as Gram stains (see later). *Nocardia* can form grains and are also filamentous, but the filaments tend to be shorter, and unlike *Actinomyces*, *Nocardia* organisms are acid-fast (however, see the previous section on [nocardiosis](#)). The filaments of other actinomycetomas (including those caused by *Actinomadura* or *Streptomyces* species) can have a close resemblance to *Actinomyces*, but the organisms of eumycetomas (e.g., *Madurella* spp. and *Phialophora* spp.) form segmented hyphae that are much broader (2–5 μm in diameter) than those of *Actinomyces* (~1 μm). Grossly, inspecting the color of the grains in lesional drainage can sometimes provide clues to the nature of the organism, which can then be supported by microscopic and culture studies. Thus, the ‘sulfur granules’ of actinomycosis are yellow, whereas most other actinomycetoma organisms are associated with light-colored grains (the yellow grains of *Streptomyces somaliensis* and the red grains of *Actinomadura pelletieri* are two exceptions), and pigmented eumycetoma organisms produce black grains.

BOTRYOMYCOSIS

Botryomycosis (bacterial pseudomycosis) is an uncommon chronic bacterial infection of the skin or viscera in which small whitish granules composed of the causal bacteria are present in areas of suppuration.^{997–999} In the skin, they are often discharged through draining sinuses. Because the lesions closely mimic clinically and histologically those of mycetoma, botryomycosis is included in this chapter.¹⁰⁰⁰

The cutaneous lesion is usually a large swollen tumor or plaque with nodular areas or ulcers and discharging sinuses.^{1001–1003} The hands, feet, head, and the inguinal and gluteal regions are most commonly involved.^{1004,1005} Multiple cutaneous lesions in different parts of the body have been described.^{1006,1007} Botryomycosis has sometimes been reported in patients with diabetes¹⁰⁰⁷ or with various abnormalities of the immune system,¹⁰⁰⁴ including AIDS.^{1006,1008–1010} It has been documented in a patient with extensive follicular mucinosis,¹⁰¹¹ at the site of localized corticosteroid injections,¹⁰¹² and in association with adamantinoma of the tibia.¹⁰¹³

Gram-positive organisms, particularly *Staphylococcus aureus*, are usually involved, but gram-negative organisms, including *Actinobacillus lignieresii* and *Pseudomonas aeruginosa*,¹⁰¹⁴ have also been incriminated.^{997,1015} A mixed growth of organisms is rarely present.

Antibiotics are used to treat botryomycosis, with the agent used depending on the sensitivity of the causative bacteria and the immune status of the host.¹⁰¹⁶

Histopathology⁹⁹⁷

The lesion resembles mycetoma, with a small granule present in the center of a suppurative zone. The granules are basophilic, usually with a surrounding eosinophilic zone that is PAS positive.⁹⁹⁷ The bacteria can be identified by a Gram stain ([Fig. 25.25](#)). In contrast to mycetoma, there are no filaments present.¹⁰⁰⁰ Transepidermal elimination of the granules has been reported.¹⁰¹⁷

The matrix of the granules contains IgG and sometimes C3 complement.^{1006,1018}

Differential diagnosis

The content of the grains of botryomycosis must be distinguished from that associated with other classes of organisms, including higher bacteria, such as actinomycetes and *Nocardia*, and true fungi. The morphology of these organisms is quite different from the agents of botryomycosis and can be evaluated through the use of PAS, silver methenamine, and acid-fast stains as well as the Gram stain (discussed previously).

Figure 25.25 Botryomycosis. A portion of a grain within an inflammatory focus in the subcutis. Note the clumps of bacteria, surrounded by an eosinophilic zone – an example of the Splendore–Hoeppli phenomenon. (H&E)

ZYGOMYCOSIS

There is an increasing tendency to use the broader term ‘zygomycoses’, which covers infections caused by all fungi belonging to the class Zygomycetes,^{1019–1022} rather than the older term ‘mucormycosis (phycomycosis)’, which is restricted to infections caused by various species in one family of the order Mucorales. However, because the infections caused by fungi within the order Entomophthorales, which is the other major group of Zygomycetes, are clinically quite different from mucormycosis, the two groups of infections are considered separately.¹⁰²³ The zygomycoses commonly affect immunocompromised individuals.¹⁰²⁴

MUCORMYCOSIS

Mucormycosis refers to opportunistic infections by fungi within the family Mucoraceae, one of the many families in the order Mucorales.¹⁰²⁵ There are three important genera responsible for human infections: *Rhizopus*, *Mucor*, and *Absidia*. These fungi are widespread in nature, particularly in soil and decaying vegetable matter.¹⁰²⁵ *Rhizopus oryzae* is the predominant pathogen in this group, but many different species in these three genera have been implicated in human infections.^{1026,1027} The genus *Lichtheimia* has been split off from *Absidia* and is a common cause of human disease; in fact, *Mucor*, *Rhizopus*, and *Lichtheimia* are the most common members of the order Mucorales to produce mucormycosis, accounting for up to 80% of all cases.¹⁰²⁸ A fourth genus in the order Mucorales, *Apophysomyces*, is only a rare cause of cutaneous disease.¹⁰²⁹ A fifth, *Rhizomucor*, is equally rare.¹⁰³⁰ Two more genera, *Saksenaea* and *Cunninghamella*, complete this family.¹⁰³¹ *Mortierella* was once included in this group, but it has now been placed in a separate family known as Mortierellaceae; these are responsible for certain bovine diseases but are not confirmed as human pathogens.¹⁰³² Several clinical categories of mucormycosis have been delineated: rhinocerebral, pulmonary, disseminated (hematogenous), gastrointestinal, and cutaneous.^{1033,1034} The cutaneous lesions may be further divided into primary and secondary types.

Primary cutaneous mucormycosis is rare and usually develops in diabetics, in patients with thermal burns, and sometimes in those who are immunocompromised.^{1020,1027,1035–1038} Toxic epidermal necrolysis has been complicated by *Mucor* infection.¹⁰³⁹ Lesions resulting from

contaminated adhesive dressings were reported in the past.^{1040,1041} Visceral dissemination may follow a primary lesion in the skin.^{1042–1045}

Secondary cutaneous mucormycosis results from hematogenous seeding from a lesion elsewhere in the body.¹⁰⁴⁶ Such patients may have underlying diabetes, leukemia, lymphoma, neutropenia, or be immunocompromised in some other way.^{1037,1046,1047} Premature infants and renal transplant recipients may be at risk.^{1048,1049}

Cutaneous mucormycosis may present as a tender indurated large plaque with a dusky center, as an area of necrotizing cellulitis,¹⁰²³ as an area of necrosis in a thermal burn, or as a lesion resembling ecthyma gangrenosum.^{1033,1050} It can mimic necrotizing fasciitis¹⁰⁵¹ or pyoderma gangrenosum.¹⁰³⁰ In one instance, a large ulcer developed in a tattoo;¹⁰¹⁹ another report documented involvement of the skin around the site of an intravenous catheter insertion.¹⁰⁵² A bull's-eye infarct developed in another patient at the site of an arterial line.¹⁰⁵³ Infection has also occurred at the site of an insect bite.¹⁰⁵⁴ Penile lesions due to *Rhizopus oryzae* and, in another instance, *Absidia corymbifera* have been reported.^{1055,1056}

Amphotericin B, in both conventional and liposomal forms, has been used to treat this disease.^{1029,1056} Itraconazole and voriconazole have also been used. The new triazole antifungal agents, such as posaconazole, have shown greater efficacy and less toxicity than amphotericin B and may become the treatment of choice.¹⁰³⁴

Histopathology¹⁰⁵⁷

The appearances are quite variable. There may be suppuration or areas of necrosis. There may be a resemblance to superficial granulomatous pyoderma, although the presence of fungal elements assists in making a distinction.¹⁰⁵⁸ Sometimes there is only a minimal inflammatory response. Hyphae often invade vessel walls, with subsequent thrombosis and infarction.^{1046,1050} Subcutaneous granulomas have been reported with some species of *Absidia*.

The hyphae are broad and usually nonseptate (Fig. 25.26). They branch at right angles, in contrast to *Aspergillus*, which usually branches at an acute angle.¹⁰²³ Sometimes the hyphae appear collapsed and twisted. They are often clearly seen in H&E-stained sections.

Differential diagnosis

In lightly stained sections with sparse numbers of organisms, causative agents of mucormycosis can be mistaken for artifact or missed alto-

gether. They must be distinguished from other organisms, particularly swollen, degenerated hyphae of *Aspergillus*. Cross-sectional profiles of zygomycete hyphae could be confused with empty spherules of *Coccidioides immitis* (discussed previously), but in contrast to *Coccidioides*, endosporulation is not seen, and other portions of the specimen are likely to show identifiable hyphal forms.

SUBCUTANEOUS PHYCOMYCOSIS

Subcutaneous phycomycosis is the established, yet somewhat unsatisfactory, designation for infections caused by fungi of the order Entomophthorales.¹⁰⁵⁹ Two genera, *Basidiobolus* and *Conidiobolus* (*Entomophthora*), are usually implicated in the infections, which typically are solitary and involve the subcutis of healthy individuals.^{1060–1062} Spontaneous resolution of the lesions sometimes occurs. Visceral spread has been reported in a renal transplant recipient.¹⁰⁶³ These infections have been mainly reported from Africa and Southeast Asia.¹⁰⁶⁴ *Conidiobolus* uncommonly causes subcutaneous disease. It has also been associated, rarely, with rhinofacial disease.^{1065,1066}

Potassium iodide or itraconazole can be used to treat basidiobolomycosis that is extensive or persistent.¹⁰⁶⁷

Phycomycoses have also been reported in animals, particularly horses ('swamp cancer').¹⁰⁶⁸ In addition to fungi from this order, aquatic fungi (particularly *Pythium* sp.) from a totally unrelated 'class' have been incriminated in equine phycomycosis.¹⁰⁶⁹ They are mentioned here because the author has seen two cases of a periorbital cellulitis in humans who had contact with horses, which were probably the source of these equine fungi.¹⁰⁷⁰

Histopathology^{1071–1077}

There is granulomatous inflammation in the dermis and subcutis, with scattered abscesses and sometimes areas of necrosis.¹⁰⁷² Broad, aseptate hyphae are identified. The most striking feature is the presence of smudgy eosinophilic material surrounding the hyphae.^{1072,1073} This resembles the Splendore–Hoeppli phenomenon seen in relation to certain metazoan parasites.^{1074,1075} Eosinophils are also present in the inflammatory infiltrate;¹⁰⁷⁶ an eosinophilic panniculitis has been described.¹⁰⁷⁸

In the author's human cases of equine phycomycosis, foci resembling the flame figures of eosinophilic cellulitis were present (Fig. 25.27). The fungi were not visualized on H&E or PAS preparations, but only with the silver methenamine stain.¹⁰⁷⁰ A specific PCR method for diagnosing *Basidiobolus* has been developed.¹⁰⁷⁹

HYALOHYPHOMYCOSIS

The term 'hyalohyphomycosis' has been applied to a heterogeneous group of opportunistic infections in which the pathogenic fungi grow in tissue in the form of hyphal elements that are unpigmented, septate, and branched or unbranched.^{657,1080} Dematiaceous fungi are excluded. Examples of hyalohyphomycosis include infections caused by *Schizophyllum commune* and species of *Acremonium*,^{1081–1083} *Pseudallescheria*,^{1084–1086} *Paecilomyces*,^{1087–1093} *Fusarium*, *Penicillium*, and *Scedosporium*.^{1094–1101} Infections caused by species of *Aspergillus* can also be accommodated in this group. One case of subcutaneous infection due to *Cephalotheca foveolata*, not previously thought to cause human infection, has been reported.¹¹⁰² Predisposing immunological disturbances are often present in individuals with these infections; immunodeficiency is not invariable.^{1082,1083,1103} A contaminated skin lotion and a dog bite were the source of infection in two cases of *Paecilomyces* infection.^{1088,1104} Preterm neonates can also be involved.¹¹⁰⁵ Cutaneous lesions may take the form of disseminated nodules,¹⁰⁸⁵

Figure 25.26 Mucormycosis. The organisms are broad and only rarely septate in this example. Some of the hyphae appear collapsed and twisted. (PAS)

Figure 25.27 Equine phycomycosis in a human. (A) Multinucleate giant cells surround zones of necrosis. There are numerous eosinophils in the infiltrate. (H&E) (B) The hyphae are quite long on silver stain. They were not seen on the PAS stain. (Grocott stain)

sporotrichoid spread,¹¹⁰⁰ crusted plaques,¹¹⁰⁴ and infection of surgical or trauma wounds.¹⁰⁸⁶

FUSARIOSIS

Fusarium sp. can produce localized cutaneous lesions or disseminated disease. Systemic fusariosis mainly occurs in immunocompromised individuals with hematological malignancies, usually with associated neutropenia.^{1106–1113} It may also occur in patients infected with HIV and occasionally in individuals with extensive burns. Trauma has also been implicated.¹¹¹⁴ Disseminated fusariosis presents with sustained fever refractory to antibacterial and antifungal therapy and also with skin lesions in 60–70% of cases. In a series of 35 patients with cancer and *Fusarium* infection, reported from the M. D. Anderson Cancer Center in Houston, Texas, 20 had disseminated infection, 6 had primary localized skin infections, 4 had skin lesions associated with sinus infections, and 5 had onychomycosis.¹¹¹⁵

Many different forms of skin lesions can be seen, and most patients have a variety of forms. There may be red or gray macules, pustules, subcutaneous nodules, ecthyma gangrenosum-like lesions with a black eschar,^{1116,1117} target lesions, lupus vulgaris-like lesions,¹¹¹⁸ vasculitic

lesions,¹¹¹⁹ and in one case a facial granuloma.¹¹²⁰ Most disseminated lesions occur on the extremities.¹¹¹⁵

Onychomycosis can occur in both immunocompromised and immunocompetent individuals.^{1115,1121} The case reported on the arm of a healthy child¹¹²² was questioned in subsequent correspondence because molecular identification was not carried out.¹¹²³ The genus *Fusarium* includes approximately 1000 species and variants.¹¹²³

The mortality rate is 50–80% because it responds poorly to formulations of amphotericin B and to itraconazole. Voriconazole has had limited success.¹¹²⁴ Granulocyte colony-stimulating factor may be necessary to facilitate bone marrow recovery.

Histopathology

There is usually a heavy acute and chronic inflammatory cell infiltrate in the dermis and/or the subcutis. Granulomas are sometimes present. Dermal necrosis may be associated with mycelia invading blood vessels with subsequent thrombosis.¹¹²⁵ The hyphae of *Fusarium* are hyaline, septate, and branched at acute or right angles. They resemble *Aspergillus*.^{1113,1118}

PENICILLIOSIS

In some Southeast Asian countries, infection with the dimorphic mold *Penicillium marneffei* has increased in importance; it is an indicator organism of advanced HIV infection.^{1126–1130} The majority of cases occur in northern Thailand or in individuals who have migrated from that area.¹¹³¹ In addition to infecting AIDS patients, it also occurs in patients with Hodgkin's disease, tuberculosis, and autoimmune diseases, including systemic lupus erythematosus.¹¹³² Infection is assumed to result from inhalation of conidia.

The majority of cutaneous lesions are umbilicated papules, resembling molluscum contagiosum.¹¹²⁶ There may be central necrosis. Brown papules and indurated macules also occur.¹¹³³ The lesions are primarily on the upper half of the body, including the oral mucosa. Fever, weight loss, anemia, and lymphadenopathy are often present. Compared to HIV-positive patients, HIV-negative patients with penicilliosis are older, more prone to have bone or joint infections, and more likely to have inflammatory skin lesions such as Sweet's syndrome; HIV-positive patients were more likely to have umbilicated skin lesions.¹¹³⁴

The fungus can readily be isolated from skin lesions, and a PCR-based method for diagnosis has been developed.¹¹³³

Treatment with amphotericin B, followed with oral itraconazole, has been used. Lifelong itraconazole may be necessary for AIDS patients to prevent recurrence of the disease.¹¹²⁶

Histopathology

There is a diffuse dermal infiltrate composed mainly of histiocytes and lymphocytes. Foamy macrophages may be abundant.¹¹³⁵ Numerous round to oval, thin-walled yeast-like organisms are scattered in the tissue or within parasitized macrophages.¹¹³³ The organisms have clear cytoplasm and round nuclei; they measure up to 5 µm in diameter. They have some resemblance to *Histoplasma* but differ by the lack of surface budding and by the presence of central division with the formation of septa within the organism.

ASPERGILLOSIS

Aspergillosis is an opportunistic infection second only to candidosis in frequency among patients with cancer.¹¹³⁶ It usually involves the lungs and only rarely the skin.^{1137,1138} Cutaneous lesions are usually part of a systemic infection in immunocompromised patients, although rarely they may be the only manifestation (primary cutaneous aspergillosis).^{364,1052,1137,1139–1147} Many patients with primary cutaneous

aspergillosis have leukemia, and lesions have developed at the sites of intravenous cannulae or of the associated dressings.^{1148–1153} Preterm infants may also develop this form of the disease.¹¹⁵⁴ There are one or more violaceous plaques or nodules that rapidly progress to necrotic ulcers with a black eschar.^{1149,1155–1157} Plaques studded with pustules are sometimes seen.^{1143,1158} Onychomycosis may also occur.¹¹⁵⁹ *Aspergillus flavus* is the most common isolate,^{1148,1160} *A. fumigatus*, *A. ustus*,¹¹⁶¹ and *A. niger* have also been responsible.^{1149,1162} Rarely, burns or pyoderma gangrenosum are secondarily infected with *Aspergillus* species.^{1163,1164}

Treatment is usually with amphotericin B, although it is not always successful. Caspofungin, voriconazole, flucytosine, terbinafine, and itraconazole have all been used at different times.¹¹⁵⁷

Histopathology

Depending on the host response, there can be a variety of changes ranging from well-developed granulomas¹¹³⁹ to areas of suppuration and abscess formation¹¹⁵⁰ or the presence of masses of fungi with a minimal mixed inflammatory cell response.¹¹³⁷ Hyphae may invade the walls of dermal blood vessels producing thrombosis and some associated necrosis.¹¹⁶⁵ *Aspergillus* species are found as septate hyphae that branch dichotomously (Fig. 25.28). They are best shown by the silver methenamine stain.

Overlying pseudoepitheliomatous hyperplasia of the epidermis has been reported.¹¹⁶⁶

Differential diagnosis of hyalohyphomycosis

Changes in hyalohyphomycosis vary, but there are often abscess formation and invasion of vessel walls by organisms, with infarction and associated changes of necrosis and connective tissue degeneration. Granulomas tend to occur in localized lesions of aspergillosis in patients who are immunocompetent or who have received antifungal therapy.¹¹⁶⁷ Diagnostic difficulties can sometimes arise due to the background changes that accompany these infections. Thus, as is sometimes true of mucormycosis, aspergillosis can show subcutaneous tissue changes that mimic the ghost cells of pancreatic panniculitis or the radially arranged crystals seen in gouty panniculitis.¹¹⁶⁸ In another recent case, a biopsy of a patient with multiple violaceous papules showed dermal edema and a dense neutrophilic infiltrate, resembling Sweet's syndrome.¹¹⁶⁹ Organisms are best seen with special stains, especially silver

methods such as GMS. *Aspergillus* organisms ideally display uniform, regularly septate hyphae, 3–6 µm in width, with right-angled branches that are dichotomous (i.e., the size is similar to those of the originating hyphae).¹¹⁶⁷ However, degenerated forms can be seen that can make specific identification difficult without culture studies. *Fusarium* organisms may be slightly wider than *Aspergillus*, and the branches arise at right angles and are constricted at the point of connection to the hyphae of origin. *Pseudallescheria* organisms are somewhat thinner than *Aspergillus* organisms, with haphazard branching and formation of vesicles and ovoid conidia.

MISCELLANEOUS MYCOSES

Only two infections are of dermatopathological importance – keloidal blastomycosis and rhinosporidiosis. Both have a limited geographical distribution.

KELOIDAL BLASTOMYCOSIS (LÔBO'S DISEASE)

Keloidal blastomycosis (Lôbo's disease, lacaziosis) is a rare, chronic fungal disease in which slowly growing keloid-like nodules or ulcerated verrucous plaques develop on exposed areas of the body.^{1170–1173} Lymph node involvement occurs in up to 10% of patients.^{1174,1175} The infection is caused by the fungus *Loboa lobo*, which is found almost exclusively in Central and South America.¹¹⁷⁶ Cases from other countries have been reported rarely.¹¹⁷⁷ The terms *Lacazia lobo* and *Paracoccidioides lobo* have been favored in some taxonomic classifications.^{1126,1178} The disease also affects dolphins, specifically the bottle-nosed dolphin (genus *Tursiops*).¹¹⁷⁹ Dolphin-to-human transmission has been reported.¹¹⁸⁰ Squamous cell carcinoma is a rare complication in chronic lesions.¹¹⁸¹

Treatment with the usual antifungal agents has not been effective, although clofazimine has shown some effect.¹¹⁷⁸ Cryotherapy and surgical excision have also been used. Posaconazole was effective in a recent case.¹¹⁸²

Histopathology^{1176,1183}

There is an extensive granulomatous infiltrate in the dermis composed of histiocytes and giant cells of Langhans and foreign body types, together with a few small collections of lymphocytes and plasma cells. There are numerous unstained fungal cells in H&E-stained preparations, both free and in macrophages, giving a characteristic 'sieve-like' appearance (Figs. 25.29 and 25.30). They have a somewhat refractile wall and measure 6–12 µm in diameter. Some budding, with the formation of short chains, may be present. The organisms are PAS positive; they do not stain with mucicarmine.

Differential diagnosis

Multiple buds can sometimes be seen around the cells of lobomycosis, which can then be confused with the organisms of paracoccidioidomycosis. However, the latter are more variable in size and have thinner walls. Chains of cells as seen in lobomycosis are not observed in North American blastomycosis, and *L. lobo* organisms are larger than either *S. schenckii* or *H. capsulatum*. Despite the alternative name for this infection (keloidal blastomycosis) and the keloid-like clinical appearance of some lesions, the microscopic features of keloid are not observed.

RHINOSPORIDIOSIS

Rhinosporidiosis is a chronic granulomatous infection caused by the hydrophilic agent *Rhinosporidium seeberi*.^{1126,1184} Although traditionally regarded as a fungus, it is now considered a protistan parasite

Figure 25.28 Aspergillosis. Note the regularly septate hyphae with dichotomous, right-angle branching. (H&E)

Figure 25.29 (A) Keloidal blastomycosis. (B) Numerous fungi with slightly refractile cell walls are present in the cytoplasm of macrophages and giant cells. (H&E)

Figure 25.30 Keloidal blastomycosis. (A) Low-power view of another case. Note the 'sieve-like' appearance created by the numerous unstained cells, both free and within macrophages. **(B)** Higher power view shows that organisms are sometimes aligned in short chains. (H&E)

belonging to the class Mesomycetozoea.¹¹²⁶ Rhinosporidiosis usually presents as polypoid lesions of the nasal and pharyngeal mucosa. Cutaneous lesions are rare, even in India, Sri Lanka, and South America, where the causative agent, *Rhinosporidium seeberi*, is endemic.^{1185–1189} Several cases have been reported from rural Georgia in the United States.¹¹⁹⁰ The skin may be affected by contiguous spread from a mucosal lesion, by autoinoculation, and rarely through hematogenous dissemination.^{1191–1193} The term 'rhinosporidioma' has been proposed for the solitary tumor-like nodule that occurs, rarely, on other parts of the body.^{1194–1196}

Histopathology¹¹⁹⁷

The large spherical sporangia (100–400 μm in diameter), containing from hundreds to thousands of endospores, each measuring up to 7 μm in diameter, are characteristic (Fig. 25.31). The sporangia may be within gigantic foreign body giant cells.¹¹⁹⁸ There is also a mixed inflammatory cell infiltrate, with the formation of some granulomas. Sporangia and accompanying spores can be seen on fine needle aspiration cytology.¹¹⁹⁹ A biopsy obtained during dapsone therapy showed degenerated organisms with hyalinized, collapsed walls, and invasion of sporangia by multinucleated giant cells.¹²⁰⁰

Figure 25.31 Rhinosporidiosis. Large spherical sporangia contain numerous endospores. (H&E)

ALGAL INFECTIONS

Algal infections are exceedingly rare. In addition to protothecosis (discussed next), the intake of the blue-green alga *Spirulina platensis* in a food supplement has produced a presumptive eruption that exhibited features of both bullous pemphigoid and pemphigus foliaceus.¹²⁰¹

PROTOTHECOSIS

Protothecosis is a rare infection caused by achlorophyllic alga-like organisms of the genus *Prototheca*.^{1202,1203} There are several species, but *Prototheca wickerhamii* is most often found in humans.^{1204,1205} It can be cultured on Sabouraud's medium, which is the usual medium used for the culture of fungi.¹²⁰⁶

Infection usually results from traumatic inoculation in an immunocompromised host.^{1207–1212} It may involve the skin and subcutaneous tissue.^{1213,1214} Infection of an olecranon bursa has been recorded.¹²⁰⁸ Rarely, there is visceral dissemination. Cutaneous lesions are eczematous,¹²¹⁵ pustular,¹²¹⁶ herpetiform,¹²¹⁷ or papules¹²¹⁸ and papulonodules that may coalesce, resulting in the formation of slowly progressive plaques.^{1208,1219,1220} Onychoprotection can also occur.¹²²¹

Treatments have included the use of amphotericin B, fluconazole, and itraconazole. Voriconazole has also been used in recent times.¹²²²

Histopathology¹²⁰⁷

The usual picture is a chronic granulomatous reaction throughout the dermis, with a variable admixture of lymphocytes, plasma cells, and occasionally eosinophils and even neutrophils.¹²²³ In early lesions, there are fewer multinucleate giant cells and the infiltrate shows greater localization to a perivascular and periappendageal position. There is focal necrosis in some lesions, particularly those with subcutaneous involvement. Epidermal changes are variable.¹²⁰⁷

Organisms (sporangia) are found in the cytoplasm of macrophages and multinucleate giant cells as thick-walled spherical bodies, often

Figure 25.32 Protothecosis. Sporangia are present in the cytoplasm of multinucleate giant cells. (PAS stain)

with a clear halo around them (Fig. 25.32). They may also be found in necrotic foci¹²²⁴ and free in the dermis, but they are difficult to see in H&E-stained preparations. *Prototheca wickerhamii*, the species usually responsible for the infection in humans, measures 3–11 μm in diameter. Many show internal septation, with endospore formation. Protothecal sporangia are much smaller than those of *Coccidioides immitis*.¹²¹⁴ They stain with the PAS and silver methenamine stains. Specific identification can be made with a fluorescein-labeled monoclonal antibody.

INTRODUCTION

Viral infections of the skin are of increasing clinical importance, particularly in patients who are immunocompromised. Viruses may reach the skin by direct inoculation, as in warts, milker's nodule, and orf, or by spread from other locations, as in herpes zoster. Many viral exanthems result from a generalized infection, with localization of the virus in the epidermis or dermis or in the endothelium of blood vessels.¹ The usual clinical appearance of this group is an erythematous maculopapular rash, but sometimes macular, vesicular, petechial, purpuric, or urticarial reactions may be seen. An erythematous-vesicular pattern is more likely to be a viral disease than the other causes of an exanthem, such as drugs and bacteria.² Some of the varied manifestations of viral diseases may result from an immune reaction to the virus. This is the probable explanation for the erythema multiforme and erythema nodosum that occasionally follow viral infections. Other dermatoses appear to be in this category of a post-viral dermatosis (see later). A new exanthem with a distinctive erythematous macular appearance has been described.³ It is of presumptive viral etiology, but no organisms could be detected by the usual means.³

Viruses are separated into families on the basis of the type and form of the nucleic acid genome, of the morphological features of the virus particle, and of the mode of replication. There are four important families involved in cutaneous diseases: the DNA families of Poxviridae, Herpesviridae, and Papovaviridae and the RNA family Picornaviridae. In addition to these four families, exanthems can occur in the course of infections with the following families: Adenoviridae, Reoviridae,⁴ Togaviridae, Flaviviridae, Retroviridae, Parvoviridae, Paramyxoviridae, Arenaviridae, Filoviridae, and Bunyaviridae.^{1,5} The three major DNA families (there are seven in all) produce lesions that are histologically diagnostic for a disease or group of diseases, whereas the other viruses, particularly the RNA viruses, produce lesions that are often histologically nonspecific. These nonspecific features include a superficial perivascular infiltrate of lymphocytes, mild epidermal spongiosis, occasional Civatte bodies, and, sometimes, urticarial edema or mild hemorrhage. These features are often given the abbreviated title of morbilliform changes, but they can also be seen in drug eruptions. Although often regarded as favoring a drug reaction, eosinophils can certainly be found in viral exanthems, particularly in older lesions. LeBoit highlighted these problems in a philosophical article a few years ago.⁶ Inclusion bodies, which represent sites of virus replication, are uncommon in skin lesions produced by viruses outside the four major families.

Various laboratory techniques can be used to assist in the specific diagnosis of a suspected viral disease.⁷ These include light and electron microscopy of a biopsy or smear, serology, viral culture, and immunomorphological methods. Negative-contrast electron microscopy allows rapid, and virus-family specific, detection of the causative virus.⁸ Although viral isolation in tissue culture remains the paramount diagnostic method, the development of monoclonal antibodies to various viruses, for use with fluorescent, immunoperoxidase, and enzyme-linked immunosorbent assay (ELISA) techniques, has made possible the rapid diagnosis of many viral infections with a high degree of specificity.⁹ Techniques using the polymerase chain reaction (PCR) are now being used routinely in some laboratories for the diagnosis of certain viral diseases. Serology is still the preferred method of diagnosis for certain viral infections, such as rubella and infectious mononucleosis. Brief mention must be made of the Tzanck smear, which was traditionally used by clinicians, especially dermatologists, in the diagnosis of certain vesicular lesions, especially those caused by the herpes simplex and varicella-zoster viruses. A smear is made by scraping the lesion. This is then stained by the Giemsa or Papanicolaou methods and examined for the presence of viral inclusion bodies. This use is declining with the advent of the more specific immunomorphological techniques.

The various virus families, and the cutaneous diseases they produce, are considered in turn after a brief discussion of the concept of the post-viral dermatoses.

Post-viral dermatoses

Dermatoses are seen, occasionally, which appear to be a reaction to an earlier viral infection. As mentioned previously, erythema multiforme and erythema nodosum sometimes follow a viral infection. At other times, the viral etiology is presumptive, such as the appearance of skin lesions some days after an upper respiratory tract or gastrointestinal infection of possible viral etiology. Serological evidence of a viral illness, such as IgM antibodies to a particular virus, is sometimes present. Although the dermatoses are thought to result from an immunological reaction to a virus, it does not necessarily persist in the body. There are circumstances, however, in which viral persistence has been demonstrated. Such is the case with the herpes simplex virus and erythema multiforme (see p. 56).

The histological pattern seen in these various post-viral dermatoses is similar – a lichenoid lymphocytic vasculitis. This pattern is characterized by a lymphocytic vasculitis, usually mild and without the presence of fibrin in vessel walls, accompanied by a lichenoid (interface) reaction in which there are variable numbers of apoptotic keratinocytes. Variations on this theme may allow a specific diagnosis to be attached to the process. For example, some cases of pityriasis lichenoides appear to follow a viral illness. On histological examination, there is parakeratosis in addition to a lichenoid lymphocytic vasculitis. In erythema multiforme, associated with herpes simplex, there is a prominent lichenoid (interface) dermatitis with cell death at all layers of the epidermis. In Gianotti-Crosti syndrome (see p. 745), associated with many different viruses, spongiosis is an additional modification to the usual pattern of lichenoid lymphocytic vasculitis.

This concept may need to be modified as additional information becomes available. In the meantime, it provides a plausible explanation of observed cases.

POXVIRIDAE

The family Poxviridae is divided into many genera, of which the genus *Orthopoxvirus* includes vaccinia virus, variola virus, cowpox virus, and at least six other species, including monkeypox virus, camelpox virus, and raccoonpox virus.¹⁰⁻¹² Only three other genera cause human disease: the genus *Parapoxvirus* causing milker's nodule, orf, and sealpox;¹²⁻¹⁴ the genus/subgenus *Molluscipoxvirus* resulting in molluscum contagiosum;¹⁵ and the genus *Yatapoxvirus* resulting in tanapox. The account presented here is limited to the following poxvirus infections:

- Cowpox
- Vaccinia
- Variola (smallpox)
- Monkeypox
- Molluscum contagiosum
- Milker's nodule
- Orf.

The causative viruses are large, with a DNA core and a surrounding capsid. There are two subgroups, based on the morphological features of the virus. The viruses of molluscum contagiosum and orf are oval or cylindrical in shape and measure approximately 150 × 300 nm. The remaining viruses are brick-shaped and range in size from 250 to 300 nm × 200 to 250 nm. Clusters of these poxviruses can be identified in hematoxylin and eosin (H&E)-stained sections as intracytoplasmic eosinophilic inclusions.

COWPOX

Cowpox is a viral disease of cattle. It may be contracted by milkers, who develop a pustular eruption on the hands, forearms, or face, accompanied by slight fever and lymphadenitis. Crusted lesions resembling anthrax¹⁶ and sporotrichoid spread¹⁷ have also been reported. Laboratory acquisition of human cowpox virus infection has been reported.¹⁸ Other unusual presentations include genital ulcerations in a child¹⁹ and chondritis involving the ear.²⁰ A generalized eruption due to cowpox infection may develop, rarely, in patients with atopic dermatitis.^{21,22} This variant, known as Kaposi's varicelliform eruption, resembles eczema herpeticum (see p. 726). A similar generalized eruption has occurred in a patient with Darier's disease.²³ The disease is of historical interest because it was the immunity to smallpox of those who had had cowpox that led Jenner to substitute inoculation with cowpox for the more dangerous procedure of variolation. Doubt has been cast on the role of cattle as a reservoir of infection in cowpox.^{16,24} It appears that the domestic cat and rodents have an important role in the transmission of cowpox virus.^{12,16,22-27} Rare cases continue to be reported from Europe^{28,29} and other areas of the world.³⁰ A case of human cowpox virus infection was apparently acquired from a circus elephant.³¹ Rapid identification can be made by an orthopoxvirus-specific PCR.²⁹ A recently developed hydrolysis probe, the TaqMan[®] probe, which enhances the specificity of quantitative PCR, has been developed for the quick and reliable detection of cowpox virus DNA.³²

One explanation for the virulence of cowpox virus is the binding of its viral protein CPXV203 to major histocompatibility class I (MHC I) proteins in the cellular Golgi apparatus, thus interfering with this antiviral defense apparatus and promoting propagation of the virus.^{33,34}

Buffalopox is a similar condition, reported in persons who milk infected buffaloes.³⁵

Histopathology

Microscopic findings include epidermal necrosis, associated with a polymorphous infiltrate that includes lymphocytes and neutrophils.¹⁹ The epithelium may be pale and swollen; some cells possess multiple nuclei.²³ Keratinocytes feature enlarged nuclei and intracytoplasmic inclusions. The latter are of two types: (1) large, homogeneous eosinophilic type A inclusions and (2) irregular, basophilic type B inclusions. The type A inclusions appear late in the cycle of viral replication, are composed of a single protein, and may be diagnostically useful.³⁶

VACCINIA

Vaccination against smallpox was carried out with the vaccinia virus, a laboratory-developed member of the poxvirus group. In previously unvaccinated individuals, a papule developed on approximately the fifth day at the site of inoculation. This quickly became vesicular and gradually dried up, producing a crust that fell away, leaving a scar. Exaggerated scarring is a rare complication.³⁷ Hypersensitivity reactions, which may be exanthematous, urticarial, and erythema multiforme-like, may also develop.³⁸ Clinically detectable immunity appears to persist for at least 20 years after smallpox vaccination.³⁹

With the eradication of smallpox, vaccination is no longer given routinely, except to military and key medical personnel.⁴⁰ As a result, generalized vaccinia infection (eczema vaccinatum),⁴¹ a serious complication of vaccination, is now of historical interest only. A review of 450,293 military vaccinations performed recently found no resulting cases of eczema vaccinatum and only 21 cases of contact transfer of vaccinia to close contacts.⁴² On the other hand, there has been a recent

report of secondary and tertiary transmission of vaccinia lesions (involving 4 people) from a U.S. military service member who was engaged in semi-professional wrestling.⁴³ In a study published in 2012, there were 115 reported cases of vaccinia transmission through contact, representing 5.4 per 100,000 vaccinees; 45% of these received laboratory confirmation. Most vaccinees, but only 8% of contact cases, were military members; the latter were generally household or intimate contacts or wrestling partners.⁴⁴ Eczema vaccinatum has many similarities to eczema herpeticum, an infection by the herpes simplex virus seen also in predisposed patients, such as those with an atopic diathesis.

Vaccinia of the labia and inner thighs has been reported as a consequence of conjugal transfer of the virus, from military personnel who received smallpox vaccination.⁴⁵ Autoinoculation to another body site is another complication of vaccination.⁴⁶

Histopathology

The appearances are similar to those of herpes simplex, zoster, and varicella, except that intracytoplasmic rather than intranuclear inclusion bodies are seen in vaccinia.

Complications of vaccination

Many cutaneous and systemic complications of smallpox vaccination have been reported.^{47,48} They are now of historical interest only, except for late complications, which may continue to be seen.⁴⁹

Late sequelae have included keloid formation, basal and squamous cell carcinoma,⁵⁰ malignant melanoma, dermatofibrosarcoma protuberans, and malignant fibrous histiocytoma.⁵¹ Dermatoses have also developed, including discoid lupus erythematosus,⁵² herpes simplex,⁴⁹ lichen sclerosus et atrophicus,⁵³ contact dermatitis, and 'localized eczema'.⁴⁸ It is possible that some of the late complications represent the chance localization of a particular lesion at the site of previous vaccination.

VARIOLA (SMALLPOX)

Variola (smallpox) epidemics have been some of the most deadly to afflict humankind.⁴⁰ Epidemics occurred in ancient China, Egypt, and India, and later in the Roman Empire.⁴⁰ Variola virus DNA has recently been identified in a 300-year-old Siberian mummy; such discoveries might provide clues to past smallpox epidemics.⁵⁴ Variola has now been eradicated.⁵⁵ The last known case occurred in Somalia in 1977. Two types were encountered: variola major, a severe form with a significant fatality rate (up to one-third of those affected),⁵⁶ and variola minor (alastrim), a mild form with a fatality rate of less than 1%. Umbilicated papules were seen. They became crusted and healed with scarring. The mechanism of the scarring remains speculative, but it has been suggested that this may have resulted from destruction of sebaceous glands.⁵⁷

Variola remains a potential threat in biological warfare because laboratory cultures of the virus still exist.⁵⁸ In 2011, the World Health Assembly decided to suspend the conversation about destroying existing stockpiles of variola virus for 3 years (the fifth such delay) in order to give researchers more time to study the virus. One reason for this scientific interest is the ability of variola virus to alter the human immune response through mechanisms that are not yet fully understood.⁵⁹

Histopathology

Variola resulted in vesicular lesions that resembled those of herpes simplex, zoster, and varicella, except (usually) for the absence of multinucleate epidermal cells and for the intracytoplasmic localization of the inclusion bodies.⁶⁰

MONKEYPOX

Human monkeypox, an emerging viral zoonosis, is caused by a member of the genus *Orthopoxvirus*. It was first identified in the Democratic Republic of the Congo (formerly Zaire) in 1970. It emerged in the United States in 2003, probably as a consequence of the shipment of small animals from Ghana to the United States.^{61,62} Much attention was initially paid to monkeypox because of its clinical similarities to smallpox.⁶¹

In Africa, monkeypox is mainly a disease of children younger than 10 years. Infection is caused mainly by contact with infected small mammals, although human-to-human transmission is not uncommon.⁶¹ Respiratory droplet transmission has also been suspected.⁶³ As with variola, the eruption of monkeypox progresses through macular, papular, vesicular, and pustular phases.⁶³ Vaccination and vaccinia virus produces approximately 85% protection against monkeypox. In the cases reported from the United States, all had contact with infected exotic or wild mammalian pets. No human-to-human transmission could be detected. No fatalities were recorded in the United States, although the mortality rate is 10–17% in African cases.⁶¹ Currently, most diagnostic assays focus on small regions of genomic DNA that may be specific for monkeypox as opposed to other orthopoxviruses.⁶³

Histopathology

At the edge of the blister, there is spongiosis and acanthosis, whereas the blister itself is an intraepidermal bulla with ballooning degeneration of keratinocytes intertwined with a mixed inflammatory cell infiltrate composed of lymphocytes and neutrophils, with a rare eosinophil.⁶² There is progression of the lesion to full-thickness necrosis of a markedly acanthotic epidermis. Rare multinucleated keratinocytes are present, but the nuclei do not show viral cytopathic changes. Follicular involvement occurs.⁶² A pustular stage then ensues.

Eosinophilic Guarnieri-type intracytoplasmic inclusions are present in affected keratinocytes. A few nuclei may have a central ground-glass appearance mimicking the inclusions of herpesvirus infections, but no true intranuclear inclusions are present. Electron microscopy confirms that the virions are in the cytoplasm of keratinocytes.⁶²

MOLLUSCUM CONTAGIOSUM

Molluscum contagiosum is a poxvirus infection of the skin and mucous membranes caused by a virus in the subgenus *Molluscipoxvirus*, which comprises four genetically distinct, but clinically indistinguishable, viral subtypes.¹⁵ Molluscum contagiosum occurs as solitary or multiple dome-shaped, umbilicated, waxy papules that range in size from 2 to 8 mm in diameter, although solitary lesions may be slightly larger.⁶⁴ There is a predilection for the head and neck, trunk, flexural areas, or the genitalia of children and adolescents.^{15,65–71} Uncommon sites of involvement include the toes,⁷² penis,⁷³ tattoos,^{74,75} burned skin,⁷⁶ and herpes zoster scars.⁷⁷ Koebnerization or linearity of lesional distribution has been described.⁷⁸

Sexual and fomite transmission may occur.^{79,80} Use of swimming pools is associated with some infections.⁸¹ Atopic dermatitis is present in more than 20% of infected patients.¹⁵ One patient with atopic eczema developed erythema multiforme-like targetoid eczema around each lesion of molluscum contagiosum.⁸² The coexistence of molluscum contagiosum and verruca plana has occurred in a patient with the hyper-IgE syndrome.⁸³ Molluscum contagiosum has also developed in patients receiving treatment with tacrolimus or methotrexate for other diseases.^{84–87}

Spontaneous regression often occurs within a year, although more persistent lesions are encountered. This regression is primarily a cell-mediated immune response because there is usually an associated

lymphocyte response. Pitted scarring is a rare complication of regression in atopic individuals.⁸⁸ Antibodies to the virus have been found in nearly 60% of patients with skin lesions, suggesting a role for humoral immunity, but antibodies are less frequent in patients with AIDS.⁸⁹ Extensive lesions can occur in immunocompromised patients, particularly those with AIDS.^{90–99} Disseminated lesions can occur in HTLV-1 infection as well.¹⁰⁰

An additional mechanism appears to be involved in regression.¹⁰¹ This involves the ubiquitin–proteasome system (UPS). Apoptosis of viral-infected cells appears to be the end point of these various mechanisms of regression. The virus may try to evade apoptosis by expressing the MC159 protein, which inhibits CD95- and TTVFR-1-induced apoptosis.¹⁰¹ Apoptosis is not increased in active lesions.¹⁰² Attenuated ubiquitination of molluscum bodies has been reported in a patient with multiple lesions in the setting of malignant lymphoma.¹⁰³

The disease is caused by a large brick-shaped DNA poxvirus with an ultrastructural resemblance to vaccinia virus.¹⁰⁴ A well-defined sac encloses the virion colony of each infected keratinocyte.¹⁰⁵ The sequencing of the viral genome is known.¹⁰⁶ The diagnosis can be made in the clinic by the use of 10% potassium hydroxide preparations.¹⁰⁷

Treatments of molluscum contagiosum include shave or surgical excision, cryotherapy, sterilized tweezers,¹⁰⁸ curettage, cantharidin, a combination of salicylic acid and glycolic acid, imiquimod,¹⁰⁹ cidofovir for recalcitrant lesions in patients with HIV,^{106,110} and injection of candida antigen into lesions as a form of immunotherapy.^{111,112}

Histopathology

A lesion consists of several inverted lobules of hyperplastic squamous epithelium that expand into the underlying dermis (Fig. 26.1).¹⁰⁴ The lobules are separated by fine septa of compressed dermis. Eosinophilic inclusion bodies form in the cytoplasm of keratinocytes just above the basal layer and progressively enlarge. At the level of the granular layer, the bodies become increasingly hematoxyphile and occupy the entire cell (Fig. 26.2). These molluscum bodies are eventually extruded with keratinous debris into dilated ostia, which lead to the surface.^{113,114} Areas of hair bulb differentiation, or epithelial proliferation mimicking a basal cell carcinoma, may occur at the margins of a lesion.¹¹³ Molluscum contagiosum has been reported in epidermal cysts,^{104,115,116} but some of these cases may simply represent pilar infundibula dilated by cornified cells and molluscum bodies.¹¹⁷

Secondary infection and ulceration may occur.¹¹⁸ Molluscum folliculitis is an uncommon pattern seen mainly in immunocompromised

Figure 26.1 Molluscum contagiosum showing inverted lobules of squamous epithelium with molluscum bodies maturing toward the surface. (H&E)

Figure 26.2 Molluscum contagiosum. The large molluscum bodies occupy almost the whole of each infected cell. (H&E)

persons.¹¹⁹ It has also followed leg shaving.¹²⁰ The molluscum bodies are present within the follicular epithelium. A variable chronic inflammatory cell infiltrate is seen in regressing lesions, and it is thought to represent a cell-mediated immune reaction.^{113,121} An inflammatory reaction surrounding molluscum lesions in HIV-positive patients undergoing highly active antiretroviral therapy may be an example of the immune reconstitution inflammatory syndrome.¹²² However, in the early eruptive phase, there is no inflammatory response.¹²³ Inflammation and a foreign body reaction may also be related to extrusion of molluscum bodies into the dermis. Rarely, an atypical lymphocytic infiltrate ('pseudoleukemia cutis', 'pseudolymphoma') may be found.^{124–127} In one case, the atypical cells were CD8⁺ T lymphocytes with scattered CD30⁺ cells.¹²⁸ In another, they were CD4⁺, with some CD30⁺ cells.¹²⁶ Still another case has shown a predominance of large, pleomorphic cells that proved to be positive for CD30; brisk Ki-67 positivity was also noted.¹²⁹ Another rare inflammatory response is a moderate to heavy infiltrate of eosinophils, with the formation of flame figures.^{130,131}

Molluscum contagiosum has also been reported in association with a nevocellular nevus, a halo nevus,^{132,133} with the Meyerson phenomenon (see p. 847),¹³⁴ with cutaneous lupus erythematosus,¹³⁵ and with

human papillomavirus (HPV).¹³⁶ Co-infection with cryptococcosis has been reported in a patient with HIV infection.¹³⁷ In one patient with systemic lupus erythematosus, metaplastic bone was present in the dermis adjacent to each lesion of molluscum contagiosum.¹³⁸

Cytologic diagnosis can be useful in that the molluscum bodies can be seen as large, discrete, blue-purple oval structures with Giemsa staining or as red-stained bodies with displacement of nuclear chromatin with Papanicolaou staining.¹³⁹ Dermoscopic examination commonly reveals an orifice and vessels that form crown, radial, flower-like, or punctate configurations.¹⁴⁰ A giant lesion of molluscum contagiosum showed what were described as 'white, shiny clods' within the nodule.¹⁴¹

Differential diagnosis

The microscopic appearance of an intact lesion of molluscum contagiosum lesions is so distinctive that a diagnosis can usually be rendered almost instantly. However, ruptured and inflamed lesions can be difficult to recognize and may require careful search or multiple levels to find the characteristic molluscum bodies. In densely inflamed lesions featuring atypical cells, and in particular a prominent CD30⁺ component, differentiation from lymphomatoid papulosis or other forms of lymphoma may be an issue. In addition to a search for molluscum bodies, PCR evaluation for possible T-cell receptor clonality may be necessary in selected cases.¹³² The reverse question – the possibility that molluscum contagiosum or other viruses could be found in lesions of lymphomatoid papulosis – has been investigated by Fernandez *et al.*; viral DNA was not identified in lymphomatoid papulosis lesions in that study.¹⁴²

MILKER'S NODULE

Milker's nodule results from infection with the paravaccinia virus, transmitted from the udders of infected cows. Indirect transmission from contaminated objects has also been reported in several patients with recent burns.¹⁴³ Lesions are usually solitary and on the hands.¹⁴⁴ Multiple nodules and involvement of other sites have been described. Lesions heal, with scarring, in 6–8 weeks. Six clinical stages have been delineated, each lasting approximately 1 week: maculopapular, target, acute weeping, nodular, papillomatous, and regressive.¹⁴⁵ However, the usual lesion, when the patient presents, is a red-violaceous, sometimes erosive or crusted nodule measuring 0.5–2 cm in diameter.¹⁴⁵ Erythema multiforme, erythema nodosum, or urticarial lesions may develop in a small number of cases.^{146,147}

The clinical and histopathological similarities between milker's nodule and human orf have led to the collective term 'farmyard-pox' being proposed for these two conditions.¹⁴⁸

Treatment is usually supportive. No trials of antiviral therapy have been published in the dermatological literature. Infection confers life-long immunity to the host.¹⁴⁴

Histopathology

The appearances vary with the stage of the lesion.¹⁴⁵ An early milker's nodule shows vacuolization and ballooning of the cells in the upper third of the epidermis, leading sometimes to multilocular vesicles.¹⁴⁹ Intracytoplasmic and, rarely, intranuclear inclusions may be seen.^{150,151} Focal epidermal necrosis sometimes occurs, and this may lead to ulceration and secondary scale crust formation. Neutrophils are found in the epidermis and superficial papillary dermis when epidermal necrosis occurs. Mature lesions will show acanthosis of the epidermis, with the formation of finger-like downward projections of the epidermis (Fig. 26.3). There is prominent edema of the papillary dermis, with an inflammatory infiltrate composed of lymphocytes, histiocytes, plasma cells, and occasional eosinophils. There are numerous small

Figure 26.3 Milker's nodule. The elongated thin rete pegs with intervening heavy inflammation of the upper dermis are characteristic features of mature lesions. (H&E)

blood vessels, many of which are ectatic, in the papillary dermis (**Fig. 26.4**). In regressing lesions, there is progressive diminution of the acanthosis and eventually of the inflammatory infiltrate.¹⁴⁵

Electron microscopy

Electron microscopy may show a large oval viral particle with a central electron-dense core surrounded by a less dense homogeneous coat and two narrow electron-dense layers. Rapid diagnosis may be made by electron microscopy of the crust from an early lesion.¹⁵¹

ORF

Orf (ecthyma contagiosum) is primarily a disease of young sheep and goats involving the lips and perioral area.^{148,152–158} It is caused by a poxvirus of the paravaccinia subgroup. Orf can be transmitted to humans by contact with infected animals; rarely, lesions have developed at sites of trauma produced by an inanimate object.¹⁵⁷ Lesions, which measure approximately 1–3 cm or more^{154,155} in diameter, develop most commonly on the hands and forearms. Other sites of involvement have included the face,^{159,160} scalp, temple,¹⁶¹ and perianal region.¹⁵⁶ Several lesions may be present in the one area. Spontaneous regression is usual after approximately 7 weeks. Recurrent lesions have been reported in immunocompromised persons;¹⁶² such lesions may be quite large.¹⁶³ A mature lesion is nodular with central umbilication and an erythematous halo. Regional adenitis, superinfection, toxic erythema, erythema multiforme, widespread lesions, or a generalized varicelliform eruption may complicate the infection.¹⁶⁴ Bullous pemphigoid, mucous membrane pemphigoid,¹⁶⁵ and a subepidermal blistering disease that was thought to be a distinct autoimmune blistering disorder¹⁶⁶ may also develop following orf.^{167,168}

Because spontaneous regression eventually occurs, treatment is not usually given in cases in which a clinical diagnosis is made. Many lesions are surgically excised or shaved as a diagnostic tool. Because large and atypical lesions may develop in immunocompromised patients, multiple treatment modalities have been used in these patients with variable results. Surgical excision, 40% topical idoxuridine application, cryotherapy, interferon, topical cidofovir, and imiquimod 5% cream have all been used.

Histopathology

The appearances vary with the stage of the disease (**Fig. 26.5**).^{152,153} Early lesions of orf show moderate acanthosis and pale vacuolated

Figure 26.4 Milker's nodule. The dermis between the thin rete pegs is vascular and inflamed. (H&E)

Figure 26.5 Orf. There is epidermal necrosis, acanthosis, and subepidermal edema. (H&E)

cytoplasm, involving particularly the upper epidermis.¹⁶⁹ Cytoplasmic inclusion bodies are usually present (Fig. 26.6).¹⁴⁸ An unusual change, which has been called ‘spongiform degeneration’, can be seen, particularly in follicular structures.¹⁴⁸ This is characterized by vacuolated cells having wispy strands of eosinophilic cytoplasm. Intraepidermal vesicles or bullae may form. The dermis contains dilated thin-walled vessels and an infiltrate of lymphocytes, macrophages, and occasional eosinophils and plasma cells.¹⁵³ Cells expressing CD30 are sometimes present in this infiltrate.¹⁷⁰ Later lesions often show epidermal necrosis, particularly in the center. Neutrophils are often found within and adjacent to the necrotic epidermis. Other biopsies may show elongated rete pegs with dilated vessels in the intervening dermal papillae. Sometimes there is an unusual proliferation of endothelial cells in the dermal papillae that may even simulate a vascular tumor (Fig. 26.7).¹⁶¹

Figure 26.6 Orf. Inclusion bodies are present in the cytoplasm of the keratinocytes in the upper epidermis. (H&E)

Eventually, the inflammatory infiltrate and epithelial hyperplasia resolve. The lesions of orf are generally regarded as indistinguishable from milker’s nodules,¹⁴⁸ although full-thickness epidermal necrosis seems to be more common in orf. Immunoperoxidase techniques using orf-specific monoclonal antibodies can be used to confirm the diagnosis, if necessary.

Electron microscopy

Electron microscopy shows an oval virus with an electron-dense core, surrounded by a laminated capsule similar to the virus of milker’s nodule (Fig. 26.8).¹⁷¹ Rapid diagnosis may be made by electron microscopy of negatively stained suspensions from the lesion. The number of virus-containing cells is greatest in the first 2 weeks of the disease; they may be absent by the fourth week.¹⁷²

Figure 26.7 Orf. The papillary dermis may be so vascular that a vascular tumor is suspected. (H&E)

HERPESVIRIDAE

More than 80 herpesviruses have been identified, 8 of which are known human pathogens.¹⁷³ There are three major subgroups within the family Herpesviridae. The α -herpesviruses are neurotropic and include herpes simplex virus (types 1 and 2) and the varicella-zoster virus (VZV).^{174,175} The γ -herpesviruses, the second major subgroup within the family, are lymphotropic and include Epstein-Barr virus, human herpesvirus 8 (HHV-8), and *Herpesvirus saimiri*. The predominant sites of latency of the third subgroup, the β -herpesviruses – cytomegalovirus and HHV-6 and HHV-7 – are not known.¹⁷⁵ Concurrent infection by two viruses of this family is a rare occurrence, seen in immunocompromised patients.^{176,177}

Type-specific identification of the two main types of herpes simplex virus can be made in paraffin sections using immunoperoxidase techniques; furthermore, VZV can be distinguished from them.^{178,179} PCR techniques can also be used.^{176,180,181}

HERPES SIMPLEX

There are two main types of herpes simplex virus – type 1 (HSV-1) and type 2 (HSV-2).^{173,182,183} Primary infection with HSV-1 usually occurs in childhood and is mild. Recurrent lesions occur most commonly around the lips (herpes labialis – ‘cold sores’). Other sites of infection include the oral cavity, pharynx, esophagus, eye, lung, and brain.^{184–186} Orofacial herpes is quite common, with an annual prevalence of approximately 15%.¹⁸⁷ Its lifetime prevalence is approximately 40%.¹⁸⁸ Women are more commonly affected than men.¹⁸⁷ It affects more than 40 million people in the United States.¹⁸⁹

Infection with HSV-2 generally involves the genitalia and surrounding areas after puberty; it is usually sexually transmitted.^{190–192} Its occurrence in children may be a consequence of child abuse.¹⁹³ Approximately 1.6 million persons are infected with HSV-2 annually in the United States.¹⁸⁹ In one study, antibodies to HSV-2 were present in nearly 5% of sexually active Turkish individuals.¹⁹⁴ The incubation period for genital lesions averages 5 days. HSV-2 may also result in generalized or cutaneous lesions of the newborn.^{195,196} The relationship between the site of infection and HSV type is not absolute.^{197,198} Sometimes herpes simplex infection masquerades as some other disease.¹⁹⁹ It may also be difficult to diagnose in immunosuppressed patients.¹⁸⁹ Genital herpes has masqueraded as a cutaneous T-cell lymphoma in two immunosuppressed patients.²⁰⁰

Once infected, a person will usually harbor the virus for life. The virus can travel along sensory nerves to infect the neurons in the sensory ganglia. Recurrent disease follows this latency in the sensory ganglia and can be stimulated by ultraviolet light,²⁰¹ trauma, fever, HIV infection,²⁰² menstruation, and stress, to name the most common factors.²⁰³ Acute skin eruptions that are positive for HSV DNA polymerase are an increasing problem in patients who undergo stem cell transplantation.²⁰⁴ No precipitating factors can be identified in some patients.²⁰⁵ Prostaglandins and diminished production of interferon- γ (IFN- γ) may play a role in the reactivation of infections.^{206,207} A study performed in 2000 found that reactivation of genital HSV-2 infection in asymptomatic seropositive persons is quite frequent.²⁰⁸ Asymptomatic perianal shedding of HSV is common in patients with AIDS.²⁰⁹

The usual lesions of herpes simplex consist of a group of clear vesicles that heal without scarring, except in cases in which secondary bacterial infection supervenes. Leukoderma may develop on the lip after herpes labialis,²¹⁰ and there is a report of hypopigmented lesions preceding the development of vesicles in an infant with intrauterine transmission of HSV-2.²¹¹ Special clinical variants²¹² include herpes folliculitis of the beard or scalp, herpetic whitlow^{213–216} (usually in

medical or nursing personnel), necrotizing and ulcerative balanitis^{217,218} and vulvitis²¹⁹ (a very rare HSV-2 complication, often associated with HIV infection), a varicella-like eruption,²²⁰ infection localized to sites of atopic dermatitis,²²¹ pulsed-dye laser treatment,²²² or photoexposure,²²³ vegetating plaques,^{224,225} hypertrophic papulonodules,²²⁶ flaccid intracorneal blisters,²²⁷ acquired lymphedema of the hand,²²⁸ and eczema herpeticum (see p. 726).²²⁹ Vegetative plaques, also termed **herpes simplex vegetans**, consist of exophytic and exudative lesions that typically occur in immunosuppressed patients and can clinically simulate malignancy.²³⁰ Severe primary or secondary infection with systemic involvement may occur in immunocompromised patients.^{231,232} It has followed meningococcal meningitis.²³³ Disseminated herpes simplex infection is a rare complication of pregnancy.²³⁴ Recurrent herpes labialis has developed during treatment of acne with isotretinoin.^{235,236} Recurrences decreased after the application of sunscreens.²³⁶ Herpes simplex virus DNA is present in lesional skin in a significant number of patients with erythema multiforme (see p. 56).^{237,238} Lymphedema of the hand is a rare complication of recurrent infection.²³⁹

HSV-1 and HSV-2 are biologically and serologically distinct. They are usually isolated using human embryonic fibroblast cell cultures.²⁴⁰ Characteristic cytopathic changes can be seen after 1 or 2 days. Rapid diagnosis of cutaneous infections of herpes simplex can be made using smears of lesions and monoclonal antibodies, with an immunofluorescence technique.²⁴¹ PCR-based tests are far more sensitive than immunofluorescence.²⁴² Reliable and convenient serological tests for antibodies against both HSV-1 and HSV-2 are now available commercially.²⁴³ These methods indicate that viral culture has significantly underestimated the number of infected individuals.²⁴³ PCR-based methods are now being used routinely in some laboratories for diagnosis.²⁴⁴ Confocal scanning laser microscopy has been used at the bedside to diagnose infection with herpesvirus.²⁴⁵

A range of antiviral agents – topical, oral, and intravenous – have been used in the treatment of herpes simplex, both HSV-1 and HSV-2.^{246–248} Topical treatment is the usual method, with oral and intravenous therapy reserved for recurrent and persistent lesions, usually in immunocompromised patients. Topical therapies include docosanol 10% cream, penciclovir 1% cream, and acyclovir (aciclovir) 5% ointment; Compeed® cold sore patch,²⁴⁹ idoxuridine 15% solution; and cidofovir 1% gel.¹⁸³ Systemic medications include valacyclovir (valaciclovir), famciclovir,¹⁸³ foscarnet, cidofovir,^{173,183} and isotretinoin for recurrent herpes simplex.²³⁶ Oral acyclovir, valacyclovir, or famciclovir are useful for prophylaxis against recurrent genital herpes infection;²⁵⁰ valacyclovir significantly reduces HSV-2 shedding.²⁵¹ Anti-herpes simplex viral prophylaxis (with acyclovir) has been recommended for patients with significant burn injury, particularly when involving the face.²⁵² Topical imiquimod has been recommended as therapy for acyclovir-resistant herpesvirus infection in immunocompromised patients.²⁵³ Experimental inhibition of HSV-1 has been produced by a sequence-specific gene-silencing process mediated by small interfering RNA,²⁵⁴ this may be a promising method of gene therapy in the future.

Histopathology

The histological appearances of herpes simplex, varicella, and herpes zoster are very similar. The earliest changes involve the epidermal cell nuclei, which develop peripheral clumping of chromatin and a homogeneous ground-glass appearance, combined with ballooning of the nucleus.²⁵⁵ Vacuolization is the earliest cytoplasmic alteration. These changes begin focally along the basal layer but soon involve the entire epidermis.²⁵⁵ By the time lesions are biopsied, there is usually an established intraepidermal vesicle (**Fig. 26.9**). This results from two types of degenerative change – ballooning degeneration and reticular degeneration. *Ballooning degeneration* is peculiar to viral vesicles. The affected cells swell and lose their attachment to adjacent cells, thus separating from them (secondary acantholysis). The cytoplasm of these cells

Figure 26.9 (A) Herpes simplex. (B) There is an intraepidermal vesicle containing ballooned, acantholytic keratinocytes in which there are intranuclear inclusion bodies. (H&E)

becomes homogeneous and intensely eosinophilic, and some are also multinucleate (Tzanck cells). Occasionally, the basal layer of the epidermis is also destroyed in this way, leading to the formation of a subepidermal vesicle. The change known as *reticular degeneration* is characterized by progressive hydropic swelling of epidermal cells, which become large and clear with only fine cytoplasmic strands remaining at the edge of the cells. These eventually rupture, contributing further to the formation of a vesicle. This change is not specific for viral infection and can be seen also in allergic contact dermatitis. Whereas ballooning degeneration is found mainly at the base of the vesicle, reticular degeneration is seen on its superficial aspect and margin.

Eosinophilic intranuclear inclusion bodies are found, particularly in ballooned cells (**Fig. 26.10**). They are more common in multinucleate cells of lesions that have been present for several days. Neutrophils are present within established vesicles. There are also moderate numbers in the underlying dermis, as well as lymphocytes. Neutrophils are prominent in the lesions of herpetic whitlow. Marked inflammation and even vasculitis have been noted in some lesions.²⁵⁶ Vegetative lesions include marked acanthosis with or without ulceration, acute and chronic inflammation and granulation tissue, in addition to herpes viropathic changes.²³⁰ In one case, biopsy of a herpes simplex lesion from a patient with pemphigus showed atypical plasmacytoid cells in

Figure 26.10 Herpes simplex. The multinucleate keratinocytes have intranuclear inclusion bodies. (H&E)

the dermal infiltrate; these were CD79a and CD138 positive but showed polytypic immunoreactivity with κ and λ light chain staining.²⁵⁷ As a rule, the dermal inflammation is more severe in herpes simplex than in zoster. Atypical lymphoid cells may be present in the infiltrate where herpes simplex complicates an underlying hematological malignancy.²⁵⁸ Atypical lymphocytes have been noted in 32 of 45 routine cases of herpes simplex submitted for microscopy.²⁵⁹ In a study reported from Graz in 2006, atypical lymphocytes were commonly present.²⁶⁰ Other findings included dense lymphoid infiltrates, angiotropism, and variable numbers of CD30⁺ and CD56⁺ cells. Two cases with a pseudolymphomatous appearance revealed a monoclonal population of T lymphocytes by PCR analysis.²⁶⁰ In another study, CD4⁺ and/or CD8⁺ lymphocytes were present in the infiltrate of herpes simplex.²⁶¹ The cells expressed both granzyme B and granulysin.²⁶¹ In a patient with chronic lymphocytic leukemia, a neoplastic infiltrate of cells occurred at the site of a florid herpes simplex infection, but this seemed to be part of a physiological response to the virus.²⁶²

Uncommonly, erythema multiforme-like changes may be seen in the adjacent skin, concurrent with a vesicle of herpes simplex. A related reaction pattern is so-called 'lichenoid lymphocytic vasculitis', a term coined for the changes seen in presumptive cases of herpes

Figure 26.11 Herpes folliculitis. There is a heavy superficial and deep dermal infiltrate of lymphocytes. A necrotic follicle is present in the upper third of the dermis. (H&E)

simplex with an immunological response (see p. 718).²⁶³ There is an upper dermal infiltrate of lymphocytes and histiocytes, with lichenoid changes in the epidermis and a dermal lymphocytic vasculitis.

Focal involvement of pilosebaceous units is not uncommon in recurrent lesions.²⁵⁵ In the variant known as herpes folliculitis,²⁶⁴ pilosebaceous involvement is the dominant lesion (Fig. 26.11). Rarely, the eccrine ducts and glands are involved (herpetic syringitis).²⁶⁵ Ballooning degeneration may involve cells of the outer root sheath of the deep portion of the follicle. A dermal inflammatory infiltrate is often present in these cases; it is heaviest in the deep reticular dermis – a so-called ‘bottom-heavy’ infiltrate.

Dermal nerves in lesional skin in both herpes simplex and herpes zoster show perineural and some intraneural inflammation. Viral antigen can be detected in these inflamed nerve twigs, indicating that they are not just passive conduits for viral spread.²⁶⁶ Perineural inflammation can also be present in quiescent lesions of herpes labialis. Schwann cell hypertrophy and neuronal necrosis with cytopathic changes may also be present.²⁶⁶ Sometimes the perineural infiltration is out of proportion to the overlying dermal inflammation.

In late lesions of herpes simplex, ulceration is often present. Ghosts of acantholytic, multinucleate epithelial cells with slate-gray nuclei on routine staining may still be seen in the overlying crust.

Recently, attention has been drawn to the histological appearance of the lesions that recur at the site of previous surgery. These vesicles are subepidermal, with an inflammatory response, complete with multinucleate giant cells,²⁶⁷ in the uppermost dermis.

A rapid cytological diagnosis of a vesicular lesion can be made by making a smear from the base of a freshly opened vesicle and staining it with the Giemsa stain. The Tzanck test, as this smear is called, is not as sensitive as PCR-based tests.²⁶⁸ Ballooned cells, some of which are multinucleate, will be seen in herpes simplex, varicella, and zoster. Immunoperoxidase stains specific for HSV-1, HSV-2, and VZV are available commercially.

Electron microscopy

Virus particles of *Herpesvirus hominis*, measuring between 90 and 130 nm, can be seen in the nuclei of the basal cells. Cells in the malpighian layer often contain other virus-related material, such as nuclear granules and capsules. Viral capsids have also been seen within the nuclei of monocytes, young histiocytes, and lymphocytes in the epidermal vesicles.²⁶⁹ Large lymphocytes are sometimes seen adjacent to keratinocytes exhibiting lytic changes, suggesting that cell-mediated immunity may be partly responsible for the epidermal damage that occurs.²⁷⁰

Differential diagnosis

Herpes simplex infection has a close microscopic resemblance to varicella and herpes zoster infection. Because they tend to occur in immunologically naive individuals (particularly children), varicella lesions tend to show less of a host reaction than seen in herpes simplex or zoster lesions. This is particularly the case in non-traumatized lesions. Further distinction can be made with differential immunohistochemical staining for herpes simplex-1 and -2 antigens and varicella-zoster antigen. Herpes simplex lesions may show some resemblance to the acantholytic lesions of pemphigus vulgaris, but the ballooned cells of herpes simplex are distinctly different from the acantholytic cells of pemphigus, which lack intranuclear eosinophilic inclusions. Lesions of Grover’s disease occasionally show intraepidermal vesiculation with plump, acantholytic keratinocytes, which in older lesions may resemble the eosinophilic, necrotic cells of late-stage herpes simplex infection. In difficult cases, careful inspection of multiple levels may reveal a few, more viable cells, with or without characteristic herpes viro-pathic changes. Immunohistochemical staining may also be helpful in distinguishing between the two disorders.

Eczema herpeticum

Eczema herpeticum is a generalized infection of the skin with the herpes simplex virus.^{271–273} A similar condition (eczema vaccinatum) occurred, in the past, with the vaccinia virus,²⁷⁴ and there is also an eczema coxsackium, which has been associated with coxsackievirus A16 and in pediatric patients with atypical hand, foot, and mouth disease due to coxsackievirus A6.²⁷⁵ The first two lesions have been grouped together as Kaposi’s varicelliform eruption. This condition occurs most commonly in association with atopic dermatitis,²⁷⁶ but it has also been reported in Darier’s disease,^{277,278} Hailey–Hailey disease,²⁷⁹ Grover’s disease,²⁸⁰ pityriasis rubra pilaris,²⁸¹ allergic contact dermatitis,²⁸² pemphigus foliaceus, seborrheic dermatitis, rosacea,²⁸³ psoriasis,^{284,285} lupus vulgaris,²⁸⁴ ichthyosiform erythroderma, and phenytoin-induced drug rash,²⁸⁶ a patient receiving facial tacrolimus treatment for atopic dermatitis;²⁸⁷ in multiple myeloma,²⁸⁸ in the Sézary syndrome and mycosis fungoides;²⁸⁹ and following thermal injury.²⁹⁰ It has also been reported in an HIV-positive patient after laser resurfacing.²⁹¹ It has been suggested that interleukin-4 (IL-4), which may be increased

in atopic dermatitis, may downregulate the response against herpes simplex virus and contribute to generalized infection.²⁹² Reduced numbers of natural killer (NK) cells and a decrease in IL-2 receptors probably also contribute.²⁹³ Experiments in a mouse model suggest that the low NK cell activity is the result of inhibition by IL-17.²⁹⁴ Despite this, fewer than 3% of atopic dermatitis patients actually develop eczema herpeticum. Evidence suggests that those atopics who are susceptible to this condition have Th2-type helper cell responses, diminished epidermal expression of filaggrin and antimicrobial peptides, earlier onset and more severe atopic dermatitis, and a history of other cutaneous infections.²⁹⁵

Histopathology and differential diagnosis

Although eczema herpeticum is characterized by the presence of multinucleate epidermal cells and intranuclear inclusions, rather than the intracytoplasmic inclusions seen in the past with eczema vaccinatum, these features are often obscured by the heavy inflammatory cell infiltrate of neutrophils and early breakdown of the vesicles. Recently formed lesions usually show the typical features of a vesicle of herpes simplex. Several newly-reported cases of eczema coxsackium showed spongiotic dermatitis, interface dermatitis with subepidermal separation, papillary dermal edema, and dermal inflammation.²⁹⁶ The multinucleated cells and intranuclear inclusions of herpes simplex infection, or the intracytoplasmic inclusions of vaccinia, were not observed.

VARICELLA

Varicella (chickenpox), caused by VZV, is a highly contagious disease with an average incubation period of 2 weeks.²⁹⁷ It is predominantly a disease of childhood. The peak incidence of infection is between 5 and 9 years of age.²⁹⁸ It is characterized by an acute vesicular eruption; bullous lesions are rare.^{299,300} Postinflammatory scarring of isolated lesions is very common, with a prevalence of just under 20%.²⁹⁸ The lesions develop in successive crops so that the rash typically consists of pocks at different stages of development. Thus, papules, vesicles, pustules, crusted lesions, and healing lesions may all be present. Secondary *Staphylococcus aureus* infections are widely reported.²⁹⁹ Varicella pneumonia may be seen in adults as a primary infection. Other complications of chickenpox include thrombocytopenia, necrotizing fasciitis, cerebellar ataxia, encephalitis, aseptic meningitis, Guillain-Barré syndrome, Reye's syndrome, Henoch-Schönlein purpura, and orchitis.²⁹⁸ In immunocompromised hosts, dissemination may occur, or large ulcerated and necrotic lesions (varicella gangrenosa) may develop; chronic verrucous lesions have also been described.³⁰¹⁻³⁰⁴ Atypical recurrent varicella also occurs in patients with hemopathies³⁰⁵ and those receiving hemodialysis.³⁰⁶ An interesting observation is the finding of marked intensification of the varicella eruption in areas of skin that are normally covered but that become sunburnt just before the eruption commences.³⁰⁷ Photodistributed varicella, mimicking polymorphic light eruption, has been reported.³⁰⁸ Involvement of the palms and soles is uncommon.³⁰⁹ Varicella has also been reported largely restricted to an area covered by a plaster cast³¹⁰ and in a patient with Kawasaki disease.³¹¹ It has developed in a patient receiving adalimumab therapy.³¹² Viral exanthems, particularly varicella, may localize early and preferentially to areas of prior inflammation.³¹³

Cutaneous lesions, usually scars, can be seen in neonates with the congenital varicella syndrome. This is a rare syndrome that occurs when a pregnant woman develops varicella before the 24th week of pregnancy. In addition to scars, aplasia cutis, neurological defects, eye abnormalities, and limb hypoplasia may be seen, but less frequently.³¹⁴ The incidence of an embryopathy after infection in the first 24 weeks of gestation is estimated at 1–2%.³¹⁵ Prenatal diagnosis of fetal varicella syndrome can be aided by serial ultrasound examination, magnetic

resonance imaging (to detect microphthalmia or cerebral lesions), and amniocentesis (to diagnose viral transmission).³¹⁶

Usually, the diagnosis of varicella is made on clinical grounds. In atypical cases, PCR for VZV can be performed.³¹² PCR testing of specimens from skin lesions is highly sensitive in diagnosing varicella in both vaccinated and unvaccinated individuals.³¹⁷ PCR from the oral cavity can also aid in the diagnosis of varicella even after lesions have apparently resolved.³¹⁷

Immunization against VZV can be carried out using the Oka strain of live, attenuated varicella. Care should be taken to ensure that recipients are not immunocompromised when receiving live vaccines; varicella may result.³¹⁸ A recent review of the universal varicella vaccination program in the United States concluded that vaccination has been less effective than the natural immunity that was present in communities before vaccine became available. In addition, the authors indicated that this program has not been cost-effective because increased herpes zoster morbidity has offset any cost savings from reduction in varicella disease.³¹⁹ Although the overall benefit of treating uncomplicated cases of varicella in otherwise healthy children has not been considered significant by some clinicians, treatment with oral acyclovir, within 24 hours of the development of the rash, is cost-effective because it allows caregivers to return to work approximately 2 days earlier.²⁴⁸ Acyclovir does not appear to alter the development of long-term immunity to VZV.²⁴⁸ The newer antiviral agents have not been extensively studied.

Histopathology

The appearances are virtually indistinguishable from those of herpes simplex, although the degree of inflammation is said to be greater in herpes simplex than in varicella-zoster lesions (Fig. 26.12).³²⁰ Direct immunofluorescence and immunoperoxidase methods,¹⁷⁸ using a monoclonal antibody specific for VZV,³²¹ and the Tzanck smear are superior to viral culture in the diagnosis of varicella zoster;³²² monoclonal antibody techniques have the advantage of specificity over the Tzanck smear.³²¹

The chronic verrucous lesions reported in immunocompromised patients show pseudoepitheliomatous hyperplasia and massive hyperkeratosis.³⁰¹ Herpetic cytopathic changes are also present in keratinocytes.

Figure 26.12 Varicella. This rather pristine intraepidermal bulla shows minimal inflammatory changes. Note multinucleated giant cells at the blister base – the target cells of a Tzanck preparation. (H&E)

Varicella can also be diagnosed by *in vivo* reflectance confocal microscopy. A recent case showed a blister with aggregates of bright cellular structures (necrotic keratinocytes) in the dark area of the blister; large, less bright structures with black, rounded elements (multinucleated giant cells); and mildly bright aggregates of cells in the surrounding epidermis (cytopathic keratinocytes) surrounded by inflammatory cells.³²³

Electron microscopy

The ultrastructural features of *Herpesvirus varicellae* are similar to those of *H. hominis*. However, colloidal gold immunoelectron microscopy using monoclonal antibodies can distinguish between the two.³²⁴

Differential diagnosis

The differential diagnosis is similar to that for herpes simplex and herpes zoster infection. Distinction from herpes simplex can be aided with immunohistochemical staining for VZV. Recognition of the uncommon verruciform lesions associated with HIV infection requires an index of suspicion and recognition of the characteristic herpetic viropathic changes in keratinocytes.

HERPES ZOSTER

Herpes zoster (shingles) is a common dermatological condition that affects 10–20% of the population during their lifetime, with an increased incidence in the elderly and in those who are immunocompromised.³²⁵ An estimated 1 million cases of herpes zoster occur each year in the United States.³²⁶ It results from reactivation of latent VZV infection. The characteristic rash has a unilateral dermatomal distribution that most often affects the thoracic and lumbar regions and sometimes the face. Any dermatome can be affected. Rare localizations have included involvement of the penis,³²⁵ the finger,³²⁷ and a recent surgical scar.³²⁸

Herpes zoster is an acute disease that occurs almost exclusively in adults. Childhood herpes zoster is uncommon and usually restricted to immunocompromised children and those with malignancies.^{329,330} It can develop in immunocompetent children as a consequence of intra-uterine VZV infection or postnatal exposure to this virus at an early age.³³¹ The illness is febrile and begins with pain in the area innervated by the affected sensory ganglia. The skin in this area becomes red, and papules soon develop.³³² These quickly transform into vesicles and then pustules. There is one report of bullous lesions.³³³ Crusts then form and, later, healing takes place. Chronic hyperkeratotic and verrucous lesions may occur in immunocompromised patients.^{334–336} Verrucous lesions have been reported in an immunocompetent child who developed chronic varicella-zoster skin infection complicating the congenital varicella syndrome.³¹⁴ Chronicity appears to be associated with a particular pattern of viral gene expression with reduced or undetectable levels of the viral envelope glycoproteins gE and gB.³³⁵ Sometimes there is residual scarring, particularly if there has been secondary bacterial infection of the vesicles. Although the virus usually causes a prodrome of pain, pruritus, or a burning sensation, uncommon presentations have included hiccups,³³⁷ eructation, the Ramsay Hunt syndrome,³³⁸ urinary and fecal retention, and sexual dysfunction.³³⁷

Herpes zoster is caused by the same virus as varicella (VZV).^{339–341} It occurs in individuals with partial immunity resulting from a prior varicella infection. With few exceptions, zoster appears to represent reactivation of latent virus in sensory ganglia, often in an immunocompromised host. There appears to be an association between herpes zoster and a family history of zoster.³⁴² The risk increases when multiple blood relatives have been involved.³⁴² The therapeutic use of arsenic trioxide can lead to reactivation of VZV.³⁴³ The virus travels through the sensory nerves to reach the skin, where it replicates in the epidermal keratinocytes. Viremia may occur, but it is not consistent.³⁴⁴

Now that a vaccine is available, it is hoped that this may lessen the incidence of herpes zoster in the future.³⁴⁵ Nevertheless, herpes zoster has been reported in a child following immunization for varicella using the Oka strain of live, attenuated varicella. This strain was recovered from lesional skin.³⁴⁶

Zoster is not highly infectious, although this has been disputed.³⁴⁷ When children are infected by adults suffering from zoster, they develop varicella and not zoster. An attack of either disease leaves the patient with some measure of immunity against both. Recurrent attacks of zoster are most uncommon.³³⁹ Many cases diagnosed as recurrent herpes zoster are probably recurrent herpes simplex.^{348,349} Herpes simplex virus has been detected by PCR in two cases with a persistent, painful papular eruption in a zosteriform pattern.³⁵⁰ Conversely, there is also evidence from PCR studies that initial herpes zoster is sometimes misdiagnosed as herpes simplex.³⁵¹ Simultaneous varicella zoster and herpes simplex infection also occurs, even in immunocompetent individuals.³⁵² PCR is the method of choice for the early diagnosis of herpes zoster.³⁵³ Disseminated herpes zoster with visceral involvement is a rare complication of AIDS and other immunocompromised states.^{341,354–356} It has also been reported in idiopathic CD4⁺ lymphocytopenia.³⁵⁷

Herpes zoster scars are prone to the occurrence of Wolf's isotopic response, which describes the development of a new skin disorder at the site of another unrelated and already healed skin disease. The diseases reported in healing/healed lesions of herpes zoster include granuloma annulare,³⁵⁸ granulomatous dermatitis,³⁵⁹ comedones,^{360,361} lichen planus,³⁶² graft-versus-host disease (GVHD),³⁶³ giant cell lichenoid dermatitis,³⁶⁴ urticaria,³⁶⁵ granulomatous vasculitis, granulomatous folliculitis, rosacea,³⁶⁶ sarcoidosis,³⁶⁷ lichen sclerosus et atrophicus, morphea, an eosinophilic dermatosis, fungal infections,³⁶⁸ pseudolymphoma,³⁶⁹ lymphoma,³⁷⁰ leukemia cutis,³⁷¹ Rosai-Dorfman disease, Kaposi's sarcoma, various skin cancers, and metastases.^{372,373} On the other hand, an example of a reverse isotopic response has been described in which a patient with lupus erythematosus who received carbamazepine therapy developed Stevens-Johnson syndrome, with sparing of skin previously involved with herpes zoster.³⁷⁴ The author considered a number of possible mechanisms for this phenomenon, such as the elicitation of a predominantly Th1 cytokine profile in previously infected skin, possibly inhibiting the immunological mechanisms responsible for Stevens-Johnson syndrome.³⁷⁴ Necrotizing fasciitis is another rare complication of disseminated cutaneous herpes zoster.³⁷⁵ VZV has been inconsistently identified in some of these post-herpetic inflammatory reactions. Virus was identified in a patient with cutaneous lymphoid hyperplasia and concomitant folliculitis and vasculitis.³⁷⁶

Post-herpetic neuralgia is a serious complication.³⁷⁷ It can cause debilitating pain and impaired quality of life.³²⁶ Rash severity appears to correlate with prolonged post-herpetic neuralgia;³⁷⁸ it is also more prevalent in patients older than 50 years of age.³⁷⁹ Severe ocular damage may result when the ophthalmic division of a trigeminal nerve is involved.³⁸⁰ If multiple dermatomes are involved, they are usually contiguous. There is one report of an immunocompromised patient in whom seven disparate dermatomes were involved (zoster multiplex).³⁸¹

The host's immune response to viral skin infections is a complex one combining the effects of NK cells, interferons, and macrophages that restrict viral replication and spread.³⁸² Both CD4⁺ and CD8⁺ T cells are also involved. For their part, the viruses produce substances that allow them to escape, in part, the host's immune recognition.³⁸² This is a complex process involving downregulation of both MHC I and MHC II pathways. Intercellular adhesion molecule-1 (ICAM-1) expression on the surface of keratinocytes allows binding to occur with a certain class of T cells (LFA-1 ligand-bearing T cells) involved in the host's response to viruses. It has been found that ICAM-1 expression is lost on VZV-infected keratinocytes, reducing their capacity to bind

with these T cells, suggesting a further immune-evasion strategy by the virus.³⁸²

The *treatment* of herpes zoster involves the use of antiviral drugs and other strategies to decrease the pain of any post-herpetic neuralgia that may develop.³⁸³ Acyclovir had been the drug of choice for many years, but now the newer drugs famciclovir and valacyclovir are preferred because of their superior pharmacokinetic characteristics and simpler dosing regimens.³⁷⁹ Acyclovir therapy ideally should be commenced within 72 hours of the onset of the rash. Administration of gabapentin in conjunction with antivirals during the acute phase may offer protection against post-herpetic neuralgia,³⁷⁹ as may corticosteroid administration, in the short term, although there is a risk of serious adverse effects. Other treatments to decrease post-zoster neuralgia include opioids, anticonvulsants such as gabapentin, tricyclic antidepressants, capsaicin cream, and lidocaine patches 5%.

The *prevention* of herpes zoster involves the use of vaccination. In 2006, the U.S. Food and Drug Administration approved the use of a live attenuated preparation of the Oka/Merck strain of VZV for clinical use. Its potency is said to be 14 times that of the varicella vaccine that preceded it.^{384,385} It boosts the recipient's immunity to VZV, reducing the chance that the individual's latent VZV will reactivate, producing zoster.³⁸³ It reduces the incidence of zoster by 50%, and in those who still contract the disease, it reduces the rate of post-herpetic neuralgia by 66%.³⁸⁴

Histopathology

The appearances resemble those described for herpes simplex. Despite the previous comment that lesions of herpes simplex are usually more inflammatory than those due to varicella-zoster infection,³²⁰ dermal inflammation may be prominent in some cases of herpes zoster, and there may occasionally be a vasculitis.³⁸⁶ If the vasculitis is severe, necrotizing lesions will be present.³⁸⁷ A granulomatous vasculitis and lesions resembling granuloma annulare may be seen in healing or healed lesions.^{388,389} These factors, as well as secondary infection, contribute to the scarring that sometimes ensues.

Eccrine duct and secretory coil involvement has been reported, but it is quite uncommon.³⁹⁰ Concomitant epidermal involvement is not always present in these cases.³⁹¹ Folliculosebaceous involvement is more common (Fig. 26.13). It is thought that exclusive folliculosebaceous involvement, in the setting of a nonvesicular eruption (i.e.,

Figure 26.13 Herpes zoster folliculitis. In this example, follicular destruction has occurred, but viroplastic changes are seen in degenerated epithelial cells of the adjacent epidermis (*left*) and follicular infundibulum (see inset). (H&E)

without initial epidermal involvement), represents early herpes zoster.³⁹² This is probably a consequence of the virus traveling via myelinated nerves to the skin that terminate at the isthmus of the hair follicles, in contrast to recurrent herpes simplex in which transport of the virus is to the epidermis, via terminal nonmyelinated nerve twigs.³⁹²

The chronic verrucous lesions show hyperkeratosis, verruciform acanthosis, and virus-induced cytopathic changes.³³⁵

The term 'herpes incognito' has been used for the cases in which the typical multinucleated cells are not encountered in routine sections.³⁹³ Such cases usually show a lichenoid lymphocytic vasculitis, often with subepidermal edema, and often with a periadnexal lymphocytic infiltrate with variable sebaceousitis.³⁹³ Deeper levels in such cases will often show more typical features.

Differential diagnosis

Staining with monoclonal antibody to varicella-zoster viral antigen can help distinguish zoster from herpes simplex. Varicella and zoster, being produced by the same virus, may be difficult or impossible to distinguish from one another in the absence of clinical information. However, exclusive follicular involvement tends to favor zoster, whereas a lack of significant inflammation in an undisturbed vesicle is more closely associated with varicella.

CYTOMEGALOVIRUS

Cytomegalovirus (CMV) belongs to the subgroup of β -herpesviruses. Like other members of the family Herpesviridae, this virus produces primary infection, latent infection, and reinfection;³⁹⁴ however, its site of latency is not known.

There are few reports of cutaneous involvement with CMV.^{395–397} A maculopapular eruption is the most common clinical presentation, and it is seen most often in patients with CMV infection who are treated with ampicillin. This is analogous to the situation in infectious mononucleosis.³⁹⁶ Urticaria,³⁹⁸ vesiculobullous lesions,³⁹⁹ pustular lesions,⁴⁰⁰ ulceration,^{401,402} including genital ulcers,⁴⁰³ keratotic lesions,⁴⁰⁴ diaper dermatitis,⁴⁰⁵ and even epidermolysis have been reported. CMV was demonstrated in the dermis in a patient with pityriasis lichenoides (PLEVA).⁴⁰⁶ Its etiological role was uncertain. Magro *et al.* reported seven adults who developed a cutaneous vasculopathy or sclerodermod changes in temporal association with recent CMV infection.⁴⁰⁷ No CMV inclusion bodies were present.⁴⁰⁷ Often, the clinical picture is quite nonspecific.^{408,409} The patients are usually immunocompromised^{399,410,411} – a clinical setting in which mixed infections with other agents, particularly herpes simplex virus, may occur.^{394,412–417} Patients with chronic renal failure are also prone to infection.⁴¹⁸ CMV infection has occurred in patients receiving temozolomide, a chemotherapeutic agent used to treat glioblastoma multiforme and anaplastic astrocytoma; this may be in part related to the profound lymphopenia that can occur with this drug.⁴¹⁹

Infants with congenital infection with CMV may present with petechiae and blue-red macular or plaque-like (so-called 'blueberry muffin') lesions, in addition to neurological abnormalities.⁴²⁰ Perineal ulcers were present in one infant.⁴²¹ The lesions resolved without specific therapy.

Ganciclovir, a guanosine analogue that selectively inhibits CMV DNA polymerase, can be used to treat infections.⁴²¹ Foscarnet and valganciclovir have also been used.⁴²² There is still a high mortality risk in patients with disseminated disease, but when there is local cutaneous infection in skin wounds, the prognosis is usually good.⁴¹⁸

Histopathology

There is usually a nonspecific dermal infiltrate. The characteristic changes are enlarged endothelial cells in small dermal vessels (Fig. 26.14).³⁹⁶ The nuclei of these cells contain large eosinophilic inclusions,

Figure 26.14 Cytomegalovirus infection. A blood vessel in the dermis contains several enlarged endothelial cells, each containing an inclusion body. (H&E) (Photomicrograph kindly supplied by Dr G Strutton)

surrounded by a clear halo. Cytomegalic changes in the absence of nuclear inclusions have been reported.⁴²³ There may also be prominent neutrophilic infiltration of the involved vessel walls, although an unequivocal leukocytoclastic vasculitis is quite rare.^{424,425} Other cells that may harbor viral inclusions include fibrocytes and macrophages. Ductal epithelial cells are rarely involved.⁴²⁶ The 'blueberry muffin' lesions associated with congenital infections are the result of dermal erythropoiesis.⁴²⁰ They may also be seen in congenital rubella infections.⁴²⁰

Monoclonal antibodies are available for use with immunoperoxidase methods, should it be necessary to confirm the diagnosis in cases with unusual histopathological changes (Fig. 26.15).^{421,427,428} PCR-based methods are also available.⁴⁰²

EPSTEIN-BARR VIRUS

Epstein-Barr virus (EBV) was discovered in 1964 in African Burkitt lymphoma cell cultures.⁴²⁹ It belongs to the human γ -herpesvirus subfamily along with HHV-8. It is best known as the causative agent of infectious mononucleosis, following which it establishes a clinically silent lifelong infection. It also causes a range of NK-cell malignancies

Figure 26.15 Cytomegalovirus infection. (A) The endothelial cells of this vessel are markedly enlarged. Several of the nuclei contain large eosinophilic inclusions. (H&E) (B) The intranuclear inclusions are highlighted by staining with monoclonal antibodies to CMV. (Immunoperoxidase)

as well as B- and T-cell lymphomas and also a hemophagocytic lymphohistiocytosis (see p. 1189), which is often fatal. Carcinomas and leiomyosarcomas may also result from EBV infection. Many of these tumors are found predominantly in Southeast Asia and Japan. They were reviewed relatively recently.^{429,430}

A cutaneous rash is seen in approximately 10% of patients with infectious mononucleosis, but this incidence increases dramatically if ampicillin is administered to the patient. It also occurs when ampicillin is used in patients with EBV reactivation.⁴³¹ The rash is usually erythematous, macular, or maculopapular. Erythema multiforme and urticaria may occur.¹ Rare cutaneous manifestations of EBV infection include a granuloma annulare-like eruption,⁴³² the Gianotti-Crosti syndrome,⁴³³ painful genital ulcers,^{434,435} oral hairy leukoplakia (OHL), and lymphoproliferative lesions in immunocompromised patients, particularly following transplantation.⁴³⁶ Although OHL is most closely associated with HIV infection, it has also been identified in a patient on long-term therapy with the anticonvulsant lamotrigine,⁴³⁷ in patients receiving topical intraoral or systemic corticosteroid therapy,⁴³⁸ and in a patient with systemic lupus erythematosus on systemic corticosteroids and mycophenolic acid.⁴³⁹ The lesions may histologically mimic malignant lymphoma, but they disappear completely in some patients after the degree of immunosuppression is lowered.^{436,440,441} EBV has also been implicated in the etiology of Kikuchi's disease^{442,443} and in an

NK-cell lymphocytosis associated with hypersensitivity to mosquito bites.⁴⁴⁴ EBV infection has also been linked to lymphoepithelioma, a poorly differentiated form of nasopharyngeal carcinoma. Although this infection typically is not identified in lymphoepithelioma-like carcinoma of the skin, a recent case did show positivity by PCR and *in situ* hybridization for EBV-encoded RNA.⁴⁴⁵

Extreme sensitivity to infection with EBV is seen in X-linked lymphoproliferative syndrome (XLP1; OMIM 308240), caused by a mutation in the *SHD2D1A* gene encoding SLAM-associated protein located at Xq25.^{446,447} A small number of cases (XLP2; OMIM 300635) are caused by mutations in the gene encoding the X-linked inhibitor of apoptosis (*XIAP/BIRC4*), which maps to the same region as the gene for XLP1.⁴⁴⁶ Both diseases have a similar phenotype with acquired hypogammaglobulinemia and a malignant lymphohistiocytosis. Early transplantation of allogeneic hematopoietic stem cells is the only means available to prevent fatal EBV complications later in life. Similar cases, in which no genetic abnormality has been detected, are sometimes seen.⁴⁴⁸

In situ hybridization for EBV-encoded small nuclear RNA (EBER) remains the gold standard for virus detection in tissue samples.⁴²⁹

Both oral and intravenous acyclovir have shown little or no clinical benefit in the treatment of uncomplicated infectious mononucleosis.²⁴⁸ Acyclovir, ganciclovir, penciclovir, famciclovir, foscarnet, zidovudine, and interferon have all been shown to have *in vitro* efficacy against the replication of EBV.²⁴⁸

Histopathology

There is usually a mild perivascular infiltrate of inflammatory cells. The changes are nonspecific. In oral hairy leukoplakia, there is frequently acanthosis of the involved epithelium. Confluent parakeratosis is seen in the horny layer, with a subcorneal band of ballooned epithelial cells having pale cytoplasm and perinuclear halos. EBV DNA can be identified in lesions, or smears from lesions, by *in situ* hybridization methods. *Candida* organisms can sometimes also be found in the epithelial surface.

Diagnosis can be made with exfoliative cytology, in which there is demonstration of three types of nuclear changes: Cowdry A inclusion bodies – an eosinophilic intranuclear inclusion surrounded by a clear space; ground-glass nuclei with peripheral margination of chromatin; and prominent peripheral clumping and margination of chromatin.⁴⁴⁹ Exfoliative liquid-based cytology with EBV *in situ* hybridization is another simple and effective diagnostic method.⁴⁵⁰

Differential diagnosis

OHL lesions can have resemblances to the changes in mucosal epithelium due to trauma (e.g., biting), white sponge nevus, or focal epithelial hyperplasia (Heck disease – an HPV-induced lesion). In addition, because *Candida* organisms, when present, are readily identifiable in OHL lesions, an assumption might be made that the lesion is primarily due to *Candida* infection. Therefore, diagnosis of OHL requires an index of suspicion, knowledge of the clinical setting (usually a degree of immunosuppression that is not necessarily profound) and HIV status, and the finding of a band of vacuolated cells with perinucleolar halos. Positive *in situ* hybridization staining for EBV can then clinch the diagnosis.

HUMAN HERPESVIRUS-6

HHV-6 is the sixth member of the family Herpesviridae to be identified. It shows closest homology with cytomegalovirus and HHV-7.⁴⁵¹ It is a member of the β -herpesvirus subfamily. Most of the reports of this infection are in the pediatric literature. The virus produces a cutaneous eruption (exanthem subitum) resembling measles or rubella

in infants.⁴⁵² The illness may be accompanied by fever. Like other herpesviruses, after the primary infection, it establishes latency in different cells and organs.⁴⁵³

HHV-6 infection in infants is said to be the most common cause of fever-induced seizures.^{451,454} In adults, infection is seen primarily in immunocompromised individuals. Its reactivation may be involved in the pathogenesis of the rash and GVHD that may follow allogeneic stem cell transplantation.⁴⁵⁵ HSV may also be reactivated in these circumstances.²⁰⁴ Although HHV-6 may play a role in multiple sclerosis and a demyelinating disease in patients with HIV infection, it plays no role in the etiology of lymphomatoid papulosis.⁴⁵⁴ Although parvovirus B19 is usually implicated in the etiology of papular-purpuric 'gloves-and-socks' syndrome (see p. 739), a case has been reported in association with HHV-6 infection.⁴⁵⁶ The Gianotti–Crosti syndrome may also be produced by HHV-6 infection.⁴⁵⁷

There are many reports of a drug hypersensitivity syndrome occurring in association with reactivation of HHV-6.^{458–460} This has been called the drug-induced hypersensitivity syndrome (DIHS) or drug rash with eosinophilia and systemic symptoms (DRESS).⁴⁶¹ It is considered further in Chapter 20 (p. 600). In one case, a fulminant hemophagocytic syndrome developed⁴⁶² and in another toxic epidermal necrolysis.⁴⁵³ HHV-7 may also act in concert with HHV-6 in producing the drug hypersensitivity syndrome.⁴⁶⁰ CMV and/or EBV have also been implicated.⁴⁶³ Their reactivation occurs in a similar sequential order to that seen in GVHD.⁴⁶⁴ The drugs initially implicated were sulfasalazine,⁴⁵⁸ allopurinol,⁴⁵⁹ and phenobarbital.⁴⁶² Many other drugs have since been implicated (see p. 600). There is some controversy regarding the role of HHV-6 and HHV-7 in the etiology of pityriasis rosea (see p. 111).⁴⁶⁵ It is possible that viral reactivation is the explanation for its detection in a number of circumstances.⁴⁶⁶

Histopathology

The cutaneous lesions of exanthem subitum are characterized by spongiosis, small spongiotic vesicles, and exocytosis of lymphocytes, sometimes producing Pautrier-like lesions. There is often edema of the papillary dermis and a superficial perivascular infiltrate of mononuclear cells.⁴⁵² Cytopathic changes, resembling those seen in herpes simplex and varicella-zoster infections, are absent. However, there is a recent case of a patient with B-cell lymphocytic lymphoma who had undergone autologous hematopoietic stem cell transplantation and subsequently developed high fever and a macular erythematous eruption. Biopsy showed a perivascular infiltrate composed of lymphocytes with large, irregularly contoured nuclei and central basophilic inclusions surrounded by clear halos. PCR performed on a frozen skin sample showed a high copy number of HHV-6.⁴⁶⁷

HUMAN HERPESVIRUS-7

HHV-7 was first isolated from a peripheral blood T cell in 1990 and isolated again in 1992 from a patient with chronic fatigue syndrome.⁴⁵⁴ HHV-7 can provide a transactivating function for HHV-6. HHV-7 is ubiquitous and infects more than 80% of children in infancy.⁴⁵⁵ It has been implicated in the etiology of pityriasis rosea (see p. 111), but reactivation of the virus is a possible explanation for its occurrence in some cases. Currently, there is no clear link between HHV-7 and any specific disease.⁴⁶⁸

HUMAN HERPESVIRUS-8

Unlike the other recently described herpesviruses (HHV-6 and HHV-7), HHV-8 does not appear to be ubiquitous.⁴⁶⁹ Its role in the etiology of Kaposi's sarcoma in HIV-positive individuals was confirmed in 1994 when unique DNA sequences were isolated from biopsies of

Kaposi's sarcoma. The virus, initially called Kaposi's sarcoma-associated herpesvirus (KSHV), was subsequently renamed HHV-8. Sequence analysis confirms that it is related to *H. saimiri*, which induces lymphoid malignancies in some primates, and to EBV.⁴⁷⁰ It is a member of the γ -herpesvirus subfamily along with these two viruses.⁴⁷¹

The role of HHV-8 in the etiology of Kaposi's sarcoma in patients infected with HIV is now beyond doubt.⁴⁷²⁻⁴⁷⁴ It has also been found in a variable but significant number of HIV-negative cases.⁴⁷⁵ The viral load of HHV-8 is relatively low in both HIV-positive and HIV-negative cases.⁴⁷⁶ HHV-8 infects the endothelial-derived spindle cells of Kaposi's sarcoma as well as CD19⁺ B cells. This latter event may be etiologically significant in the causation of some cases of Castleman's disease (see p. 1139) and primary effusion lymphoma.⁴⁷⁷ It has also been found in lymphomas and in other lymphoproliferative disorders with heterogeneous presentations.⁴⁷⁸ This subject has been reviewed elsewhere.^{477,478} Its presence in a surprising number of skin cancers, and in lesions of pemphigus, has not been satisfactorily explained, although tropism for lesional skin has been postulated.⁴⁷⁹⁻⁴⁸¹ Other studies have failed to confirm these findings.^{482,483} It is not associated with pityriasis rosea.⁴⁸⁴

Most studies suggest that the mode of spread is by sexual transmission, but other modes of spread are also likely.⁴⁸⁵ This is supported by its seroprevalence in pediatric populations.⁴⁷¹

PAPOVAVIRIDAE (PAPILLOMAVIRIDAE)

Papovaviruses (papillomaviruses) are DNA viruses that replicate in the nucleus. The only important virus in this group in dermatopathology is HPV, which produces various types of warts on different parts of the skin.⁴⁸⁶⁻⁴⁹⁰ The use of newer techniques, such as DNA hybridization, has allowed the separation of more than 120 antigenically distinct strains of HPV.^{491,492} Further genotypes have been identified but not fully characterized.⁴⁹³ PCR is now used routinely for the typing of HPV. In recent years, attempts have been made to relate specific antigenic strains of HPV to particular clinicopathological groups of verrucae.^{494,495} Some strains have oncogenic potential, and the theoretical mechanisms by which HPV may cause cancer have been reviewed,⁴⁹⁶ as has the role of the various immune defense mechanisms to these oncogenic and other strains of HPV.^{497,498} The following correlations have been recorded: HPV-1 – plantar warts,^{499,500} but also common warts and anogenital warts; HPV-2 – common warts, but also plantar,⁴⁹⁹ oral,⁵⁰¹ and anogenital lesions; HPV-3 – plane warts and epidermodysplasia verruciformis; HPV-3 (variant) – common warts;⁵⁰² HPV-4 – plantar and common warts; HPV-5 – epidermodysplasia, which in cases associated with this strain of HPV is usually complicated by carcinoma; HPV-6 – anogenital warts and also epidermodysplasia; HPV-7 – warts in meat and fish handlers;⁵⁰³⁻⁵⁰⁷ HPV-8, -9, -10, -12, -14, -17, -19, -22, -24, and many others – epidermodysplasia; HPV-11 – anogenital lesions;⁵⁰⁸ HPV-13 and -32 – focal epithelial hyperplasia (Heck's disease);^{509,510} HPV-57 – plantar epidermoid cysts and nail dystrophy, cutaneous verrucae;⁵¹¹⁻⁵¹³ HPV-60 – plantar warts and epidermal cysts, and papular and nodular lesions on the extremities;^{514,515} HPV-63, -65, and -66 – plantar warts;⁵¹⁶ and HPV-75, -76, and -77 – common warts in immunosuppressed patients.⁴⁹³ HPV-63 appears to have an eccrine-centered distribution in plantar skin.⁵¹⁶ There is now great interest in the role of HPV-16 and -18 in the etiology of uterine cervical intraepithelial neoplasia (CIN) and invasive carcinoma of the cervix. HPV-16 is also the strain most frequently implicated in the etiology of Bowenoid papulosis – a disease that sometimes progresses to invasive carcinoma. HPV-16 has also been detected in anogenital warts⁵¹⁷ and in a squamous cell carcinoma of the finger.⁵¹⁸ Various HPV strains may be present in immunosuppressed patients⁵¹⁹ and in skin tumors removed from them.⁵²⁰⁻⁵²³ They may also be found in the skin tumors of immunocompetent individuals.⁵²⁴ Individuals whose immunosuppression

results from HIV infection have an increased prevalence of HPV infections, a more rapid progression of the disease, and a higher number of invasive carcinomas.⁵²⁵ Studies have detected HPV strains usually associated with epidermodysplasia verruciformis in some of the malignant and premalignant skin lesions of renal transplant recipients.^{526,527} This was not found in an earlier study.⁵²⁸ Furthermore, HPV-5 has recently been found in psoriatic skin lesions, but it is not known if it has any etiological role (see later).

The traditional classification of verrucae will be used here:

- Verruca vulgaris or common wart
- Palmoplantar warts, including superficial and deep types
- Verruca plana
- Epidermodysplasia verruciformis
- Condyloma acuminatum.

Note that there is some clinical and histological overlap between these groups.⁵²⁹ Focal epithelial hyperplasia and Bowenoid papulosis are also discussed.

VERRUCA VULGARIS

The common wart (verruca vulgaris) occurs predominantly in children and adolescents, although adults are also frequently infected.⁵³⁰ Warts have been found in approximately 20% of school students.⁵³¹ The lesions may be solitary or multiple, and they are usually found on exposed parts, most frequently on the fingers.⁵³² Uncommonly, verruca vulgaris occurs on covered areas, such as axillae, groins, or genital areas.⁵³³ They are hard, rough-surfaced papules that range in diameter from approximately 0.2 cm to as much as 2 cm. New warts may form at sites of trauma (Koebner phenomenon), although not so frequently as in cases of plane warts. They are preferentially associated with HPV-2 but may be induced by HPV-1, HPV-4, HPV-27, and, uncommonly, HPV-7.^{509,534} HPV-57 has been reported to produce multiple, sometimes recalcitrant cutaneous verrucae;⁵¹³ it is not uncommon in patients with HIV infection.⁵³⁵ In children, HPV-6 and/or -11 are rarely found in common warts,⁵³⁶ whereas HPV-75, -76, and -77 have been identified in lesions from immunosuppressed patients of all ages.⁴⁹³ Disseminated HPV-11 infection has also been reported in a patient with pemphigus vulgaris receiving various treatments.⁵³⁷ Extensive verrucae have been reported in immunodeficiency syndromes, including CD4⁺ T-cell lymphocytopenia.⁵³⁸⁻⁵⁴¹ They may clear following the use of highly active antiretroviral therapy (HAART).^{542,543}

Whereas the vast majority of genital warts in adults are due to HPV-6 and -11, this is not so in young girls, in whom the occurrence of these strains raises the question of sexual abuse. In one study of 29 genital warts in girls younger than 5 years of age, 41% were due to HPV-2 and the remainder to HPV-6/11.⁵⁴⁴ Lesions positive for HPV-2 often show the marked hyperkeratosis typical of verruca vulgaris in other sites.⁵⁴⁴

An interesting observation of uncertain significance is the finding that the antimicrobial peptide LL-37 is expressed by keratinocytes in verruca vulgaris and also condyloma acuminatum.⁵⁴⁵

Various therapies have been used, including electrocautery, surgical excision, laser therapy,⁵⁴⁶ cryotherapy, double-freeze cryotherapy, duct tape with or without salicylic acid beneath this occlusive product, and other keratolytic agents. Over-the-counter salicylic acid is the most cost-effective treatment.⁵⁴⁷ Other topical therapies have included cantharidin, trichloroacetic acid, imiquimod 5% cream, ketoconazole, tretinoin cream, and podofilox.⁵⁴⁸⁻⁵⁵⁰ Extensive and recalcitrant lesions have also been treated with oral acitretin. Warts have also been successfully managed by homeopathy and by hypnosis.⁵⁴⁶ The smoke of burnt leaves of the tree *Populus euphratica* may be as effective as cryotherapy for the treatment of hand and foot warts.⁵⁵¹ It has long been used in rural Iran for the treatment of warts.

Histopathology⁵⁵²

Common warts show marked hyperkeratosis and acanthosis. There is often some inward turning of the elongated rete ridges at the edge of the lesion (Fig. 26.16). There is some papillomatosis, but this is particularly prominent in filiform variants (Fig. 26.17). Columns of parakeratosis overlie the papillomatous projections. Sometimes there is a small amount of hemorrhage within these columns. The granular layer is lacking in these areas, but elsewhere it is thickened, with the cells containing coarse clumps of keratohyaline granules (hypergranulosis). A characteristic feature is the presence of large vacuolated cells in the more superficial parts of the malpighian layer and in the granular layer. These cells (koilocytes) have a small pyknotic nucleus surrounded by clear cytoplasm. There may be small amounts of keratohyaline material in the cytoplasm. These vacuolated cells are not seen in older lesions. Warts in renal transplant recipients express keratin 13 (K13) at a much higher rate than do warts from immunocompetent individuals.⁵⁵³

Cells with pale cytoplasm, representing trichilemmal differentiation, may be seen in the lower epidermis and follicular infundibula of old warts. This has led to controversy regarding the specificity of the appendageal tumor known as tricholemmoma (see p. 908).⁵⁵⁴ It seems likely that tricholemmoma is a specific entity but that local areas of similar appearance can be seen in old warts, particularly if they involve

the follicular infundibulum.⁵⁵⁵ A similar controversy surrounds the presence of squamous eddies in old warts and the relationship of these lesions to inverted follicular keratosis (see p. 906).⁵⁵⁴ Sebaceous differentiation may rarely be seen. Acantholytic dyskeratosis has been reported in the viral warts that developed in a boy with Darier's disease.⁵⁵⁶

The nuclei of some of the cells in verruca vulgaris may also be vacuolated. They may contain basophilic inclusions representing viral inclusion bodies, or eosinophilic material that is possibly nuclear debris. Papillomavirus antigen can be detected by immunoperoxidase methods.⁵⁵⁷

Most warts show few changes in the dermis, although dilated vessels often extend into the core of the papillomatous projections. A review of 500 verrucae at the Mayo Clinic showed that 8% had a lymphocytic dermal infiltrate, with lichenoid features.⁵⁵⁸ The patients were usually elderly. The authors suggested that this might represent an immunological response, although there was no clinical evidence of regression. Rarely, a dense inflammatory cell infiltrate is present in the dermis. Up to 10% or more of these cells may be CD30⁺.⁵⁵⁹ Earlier observations suggested that the regression of common warts followed the lesions turning black, a result of thromboses in the capillaries and venules in the upper dermis, accompanied by hemorrhage. However, another study found that in all but one instance, regression took place without the lesions turning black.⁵⁶⁰ These verrucae had a heavy mononuclear cell infiltrate in the dermis, with features of a lichenoid tissue reaction. Civatte bodies were not confined to the basal layer. The findings suggest that cell-mediated regression may occur in common warts, similar to that described in plane warts. Warts treated with injections of bleomycin show confluent epidermal necrosis, single apoptotic keratinocytes, and diffuse neutrophil infiltration of the epidermis, with abscess formation in the granular layer.⁵⁶¹

Carcinoma *in situ*^{562,563} and squamous cell carcinoma have developed only very rarely in common warts.^{539,554,564} Some of the squamous cell carcinomas that develop in renal transplant patients arise in warts. In one study of renal allograft recipients, only 6% of warts removed from these patients showed dysplastic (atypical) changes.⁵⁶⁵ Multiple, huge cutaneous horns have been reported overlying a verruca vulgaris induced by HPV-2.⁵⁶⁶

Electron microscopy

Wart virus particles range from 45 to 55 nm in diameter. They are initially seen in the nucleus.

PALMOPLANTAR WARTS

Palmoplantar warts are found on the palm of the hand or sole of the foot, and they are of clinical importance because they are often painful. They usually occur beneath pressure points, where they may be confused with callosities. They are preferentially associated with HPV-1 or HPV-4 infection,⁵⁰⁹ although other subtypes, including HPV-45, -57, -60, -63, -65, and -66, have been incriminated (see later).⁵⁶⁷ Warts on the palms and soles have traditionally been divided into superficial (mosaic) warts, which are ordinary verrucae, and a deep variety (myrmecia – so named for its supposed resemblance to an anthill). Several other variants⁵¹⁴ have been described:

1. A nodular form with retention of the surface ridge pattern ('ridged wart') associated with HPV-60;⁵⁶⁸ this HPV type has also been associated with epidermal cysts on the soles,⁵⁶⁹ as has HPV-57.⁵¹¹ HPV-60-induced warts are often pigmented.^{570,571}
2. A pigmented verrucous variant associated with HPV-65
3. A whitish punctate keratotic wart, usually multiple, showing endophytic growth and associated with HPV-63.⁵⁷³ Cyst formation is sometimes present.⁴⁹³
4. A large plantar wart caused by HPV-66.⁵⁷³

Figure 26.16 (A) Verruca vulgaris. (B) Note the papillomatosis, large keratohyaline granules, and the characteristic inturning of the rete pegs. (H&E)

Figure 26.17 (A) Verruca vulgaris of filiform type. (B) There is marked papillomatosis. (H&E)

A survey over recent decades has shown that persons who are HIV positive are significantly more likely to have plantar verrucae than are those who are HIV negative, and this increased likelihood has not significantly changed over time.⁵⁷⁴

HPV type also appears to influence the natural course of plantar warts and their response to therapy. Thus, 'cures' after a wait-and-see approach were eight times higher for HPV1-associated plantar warts than for HPV-2/27/57-associated warts. Cure rates following cryotherapy and salicylic acid treatment were 65 and 92%, respectively, for HPV-1-associated plantar warts and 11 and 25%, respectively, for HPV-2/27/57-associated plantar warts.⁵⁷⁵

Histopathology

There are many similarities between the usual variant caused by HPV-1 and the common wart, except that the greater part of the lesion lies deep to the plane of the skin surface and intrudes well into the dermis.⁵³² There is prominent hyperkeratosis. The HPV-60-associated lesions show acanthosis but only mild papillomatosis.⁵⁷⁶

It is now accepted that there are correlations between certain HPV types and specific cytopathic changes:^{514,572}

- HPV-1 – Vacuolated cells in the upper epidermis with large eosinophilic keratohyaline granules (granular inclusions) (Fig. 26.18)
- HPV-2 – Condensed heterogeneous keratohyaline granules
- HPV-4 – Large vacuolated keratinocytes with almost no keratohyaline granules and small peripherally located nuclei
- HPV-60 and HPV-65 – Eosinophilic, homogeneous, and solitary inclusions, sometimes seen also with HPV-4 (homogeneous inclusions)
- HPV-63 – Intracytoplasmic, heavily stained keratohyaline material with filamentous structures that may encase the vacuolated nucleus (filamentous inclusions). Similar inclusions have recently been reported with an HPV genotype that could not be characterized but that was not HPV-63.^{577,578}

Regression of plantar warts is usually associated with thrombosis of superficial vessels, hemorrhage, and necrosis of the epidermis. There is often a mixed inflammatory cell infiltrate.⁵⁷⁹ Pigmented warts are associated with one of the related types of HPV (HPV-4, -60, and -65). The pigmentation is due to the presence of 'melanin blockade melanocytes', resulting from a failure of the transfer of melanosomes

Figure 26.18 Verruca plantaris. This example shows extensive vacuolization of cells in the superficial epidermis, with large and eosinophilic keratohyaline granules. (H&E)

to keratinocytes.⁵⁸⁰ As a consequence, melanocytes become highly dendritic and engorged with melanin pigment.⁵⁸⁰

VERRUCA PLANA

Plane warts (verrucae planae) are flesh-colored or brownish, flat-topped papules, a few millimeters in diameter. They occur most frequently on the back of the hands and on the face. The warts are preferentially associated with HPV-3 and HPV-10,⁵⁰⁹ HPV-5 is rarely involved in patients with HIV infection.^{581,582} Multiple plane warts have been reported in a patient with idiopathic CD4⁺ T-cell lymphocytopenia.⁵⁸³ They may develop at sites of trauma (the Koebner phenomenon). Plane warts may disappear suddenly after a few weeks or months, or they may persist for years. Involution is usually preceded by an erythematous change in the warts,⁵⁸⁴ but other presentations have included the development of depigmented haloes⁵⁸⁵ and the sudden eruption of large numbers of tiny plane warts.⁵⁸⁶ The regression is probably the result of cell-mediated immune mechanisms.^{587,588} The epidermodysplasia verruciformis induced by HPV-3 and HPV-10 is characterized by widely disseminated plane warts or large brownish plaques (see later). In these circumstances, the warts persist as a result of impaired cell-mediated immunity.⁵⁰⁹

Histopathology

There is hyperkeratosis and acanthosis, with vacuolation of the cells of the granular and upper malpighian layers. The stratum corneum has a 'basket-weave' appearance (Fig. 26.19). The dermis is usually normal. In spontaneously regressing warts, there is a superficial lymphocytic infiltrate in the dermis with exocytosis of these cells into the epidermis.⁵⁸⁴ This is accompanied by the death of single epidermal cells by the process of apoptosis.⁵⁸⁹ Often, more than one lymphocyte is in contact with a degenerating epidermal cell. These latter cells are shrunk, with eosinophilic cytoplasm and pyknotic nuclear remnants. Regressing plane warts lose their histological features.

One study showed that wart-specific HPV DNA can be detected on the lens of a dermoscope prior to examination with a frequency of 43%, suggesting previous contamination. Cleansing with an antiseptic wipe was apparently not

Figure 26.19 Verruca plana. There are vacuolated cells in the upper epidermis and a basket-weave pattern in the overlying stratum corneum. (H&E)

efficient in removing HPV DNA. The authors concluded that transmission from dermoscope to patients cannot be ruled out.⁵⁹⁰

EPIDERMODYSPLASIA VERRUCIFORMIS

Epidermodysplasia verruciformis (EV; OMIM 226400) is a rare autosomal recessive genodermatosis due to mutations in *EVER1/TMC6* or *EVER2/TMC8*, two adjacent genes located at 17q25.⁵⁹¹⁻⁵⁹³ Autosomal dominant inheritance has also been reported, in which *EVER1* and *EVER2* mutations are lacking;^{594,595} this indicates a degree of heterogeneity in this disease. The two genes involved in recessive disease encode transmembrane proteins located in the endoplasmic reticulum, which are likely to function as modifiers of ion transporters and to be involved in signal transduction.⁵⁹³ The *EVER* genes are members of the transmembrane channel-like (*TMC*) gene family, which comprises eight genes (*TMC1* to -8). *EVER1* and *EVER2* are identical to the *TMC6* and *TMC8* genes, respectively.⁵⁹³ Homozygosity for a c.917A→T (p.N306I) polymorphism in the *EVER2* gene was detected in two sisters with the syndrome who were originally described by Wilhelm Lutz in 1946.⁵⁹⁶ There is a susceptibility to specific strains of HPV (the so-called β papillomaviruses), which led to the development of disseminated plane wart-like lesions and, in some patients, lesions resembling pityriasis versicolor. Some of the HPV genotypes, mainly HPV-5, have oncogenic potential, leading to the development of Bowen's disease and squamous cell carcinoma, mainly on sun-exposed areas. Individuals with EV are not prone to other infections – viral, bacterial, or fungal – or abnormally susceptible to other HPV infections, although concurrent HPV infection with non-EV strains has been reported.⁵⁹⁷ Orth has called EV a primary deficiency of intrinsic immunity against certain papillomaviruses.⁵⁹³

Only 75% of patients with EV carry mutations in the *TMC6* or *TMC8* genes. This suggests genetic heterogeneity with the involvement of other genes (see later).^{593,598} EV has also been reported in patients with HIV infection⁵⁹⁹⁻⁶⁰³ and in the setting of GVHD⁶⁰⁴ and CD8⁺ T-cell lymphocytopenia.⁶⁰⁵ These cases may be linked to the unmasking or growth of EV-HPV strains or the possession of a haplotype that represents susceptibility alleles to EV-HPVs. Defective Fas function and variation of the perforin gene were found in another patient lacking *TMC* mutations.⁶⁰⁶ Recently, a number of reports have described a link between Merkel cell carcinoma, Merkel cell polyomavirus, and a variant form of EV.⁶⁰⁷⁻⁶¹⁰ In one report, family members with EV lacked *EVER1* and *EVER2* mutations but variably presented

with verruca plana-like lesions and Merkel cell carcinomas presenting at an early age. In several studies, Merkel cell polyomaviral DNA (MCPyV DNA) was found in EDV skin lesions by PCR methods.^{609,610} It has been proposed that patients with EDV may have particular difficulty clearing MCPyV infections.^{609,610}

EV usually begins in infancy or childhood.⁶¹¹ More than 20 different human papillomavirus types (β papillomaviruses) have been incriminated, including HPV-3, -5, -8-10, -12, -14, -15, -17, -19-25, -28, -29, -36-38, -46, -47, -49, -50, and -59.⁴⁹³ Two forms of the disease are currently recognized.⁶¹² One form is induced by HPV-3 and sometimes HPV-10; these virus types are also responsible for plane warts.⁵⁰⁹ Not surprisingly, this form is characterized by multiple plane warts, but the disease is distinguished by the persistence of the lesions, their wider distribution, and the presence of plaques. The distinction between this type of EV and multiple plane warts is not always clear-cut. Severe vegetating lesions are uncommon.⁶¹³ Some of the cases are familial. There may be disturbed cellular immune function.⁶¹⁴⁻⁶¹⁷ There is no tendency to malignant transformation in this form. Regression of the lesions has been reported.⁶¹² The exact status of this type of EV is controversial.

The second form of EV is related to HPV-5 and sometimes HPV-8, -9, -14, -20, -24, -38, -47, and others.⁶¹⁸⁻⁶²¹ Two susceptibility loci have been mapped to chromosome regions 2p21-p24 and 17q25.⁶²² 17q25 is the site of the *EVER1/TMC6* and *EVER2/TMC8* genes, as mentioned previously. This latter region also contains a susceptibility locus for psoriasis (PSORS2), which is of interest in view of the finding of some EV-related strains of HPV in patients with psoriasis (see later).⁶²³⁻⁶²⁵ The gene located at 2p21-p24 has not been identified, but it has been reported as a second locus in a French family with EV.⁵⁹³ In addition, X-linked recessive inheritance (OMIM 305350) and vertical transmission have also been reported.^{626,627} In addition to the plane warts, reddish-brown patches and lesions resembling scaling pityriasis versicolor and seborrheic keratosis develop,^{628,629} with the eventual complication of Bowen's disease⁶³⁰ or invasive squamous cell carcinoma. Malignant transformation, which occurs in 25-50% of patients with EV, depends on the oncogenic potential of the infecting virus.^{509,631} This is highest for HPV-5, followed by HPV-8.^{632,633} Carcinomas develop mainly in light-exposed lesions.^{634,635} Such tumors have a very low rate of metastasis,⁶¹⁸ although patients with advanced squamous cell carcinomas have a much higher rate.⁶³⁶ Patients with this oncogenic form of EV have an altered NK-cell cytotoxic response.⁶¹⁸ p53 protein expression is common in lesional skin.⁶³⁷ This form of EV has been reported in a patient who developed intestinal lymphoma.⁶³⁸ β -Papillomavirus DNA has been detected in some cutaneous squamous cell carcinomas in immunocompetent individuals.⁶³⁹

An EV-like syndrome was reported in a patient with depressed cell-mediated immunity, primary lymphedema, disseminated warts, and anogenital dysplasia.⁶⁴⁰ However, only non-EV-HPV strains were isolated from the warts and anogenital region.⁶⁴⁰ In sporadic case reports, EV has been associated with cutaneous T-cell lymphoma,⁶⁴¹ NK/T-cell lymphoma,⁶⁴² and plasmablastic lymphoma.⁶⁴³

Some of the HPV types involved in epidermodysplasia verruciformis have been implicated in other conditions. For example, HPV-8 has been found in actinic keratoses in patients without EV.⁶⁴⁴ Other EV-related HPV strains have been reported in patients with non-melanoma skin cancer.^{645,646} HPV-5 has been found on the skin, and on hairs, of both normal and immunocompromised individuals and also in lesional skin of psoriasis.^{623,647-651} EV-HPV strains have been found in a large number of patients with HPV vulvitis, a disputed entity in which genital-mucosal HPV strains have not been detected.⁶⁵² These EV-HPV strains have also been detected in vulvar and vaginal melanomas.⁶⁵³

Finally, neurological manifestations and isolated IgM deficiency have been reported in patients with epidermodysplasia verruciformis.^{654,655}

The use of sunscreens is recommended, particularly in patients harboring oncogenic strains of HPV. Therapy with electrodesiccation, cryotherapy, topical retinoic acid, and surgery are generally unsatisfactory.⁶⁵⁶ Treatment with a combination of retinoids and IFN- α -2a has given only irregular and transient results.^{593,656} However, a trial of systemic low-dose isotretinoin maintained remission status in one patient with EV.⁶⁵⁷ Treatments with imiquimod,^{658,659} tacalcitol ointment,⁶⁶⁰ and oral cimetidine⁶⁶¹ have also been reported. Remission of an EV-like eruption occurred in an HIV patient after the commencement of HAART.⁶⁶² Radiotherapy has been used for large squamous cell carcinomas.⁶⁶³

Histopathology⁶⁶⁴

The cases induced by HPV-3 resemble plane warts. In the other form, there is some variability in the changes seen. Some lesions may resemble plane warts, whereas others consist of thickened epidermis with swollen cells in the upper epidermis (Figs. 26.20 and 26.21). This latter change is a specific cytopathic effect seen in the various HPV types associated with epidermodysplasia verruciformis. Its full expression is

Figure 26.20 Epidermodysplasia verruciformis. The epidermal changes resemble, somewhat, a condyloma acuminatum. Squamous cell carcinoma was present in a neighboring area. (H&E)

Figure 26.21 Epidermodysplasia verruciformis in a patient with HIV infection. Large pale keratinocytes are present. (H&E)

characterized by large cells, sometimes in nests, in the granular and spinous layers. There is a conspicuous perinuclear halo.⁶⁶⁴ The nucleoplasm is clear, and the cytoplasm, which has a blue-gray pallor, contains keratohyaline granules of various sizes and shapes.⁶⁶⁵ The horny layer is loose and has a basket-weave-like appearance.⁶⁶⁵ Dysplastic epidermal cells may be seen. Changes of Bowen's disease or squamous cell carcinoma may ultimately supervene.

Foci of histological changes of EV have been noted in five benign skin lesions. PCR-based methods detected EV-HPV types in three of the five lesions.⁶⁶⁶ The term **EV acanthoma** was proposed for these lesions.⁶⁶⁶

CONDYLOMA ACUMINATUM

Although condyloma acuminatum is traditionally defined as a fleshy exophytic lesion of the anogenital region,^{667,668} it is now known that small inconspicuous lesions may occur on the penis,^{669–671} vulva, and cervix.^{672–674} The prevalence of HPV infection in the glans/corona region is significantly higher in uncircumcised men than in circumcised men.⁶⁷⁵ Condylomas are usually sexually transmitted and spread rapidly.⁵⁰⁸ Extensive lesions may occur in immunosuppressed persons.⁶⁷⁶ Topical corticosteroids and tacrolimus used in the treatment of vulval dermatoses may lead to the reactivation of latent HPV after prolonged therapy.^{677,678} The incubation period is variable but averages 2 or 3 months.⁶⁷⁹ Lesions resembling condyloma acuminatum have been reported as an unusual complication of intertrigo⁶⁸⁰ and of healed herpes progenitalis.⁶⁸¹ A giant-sized condyloma, related to HPV-6 and -11, has been reported on the breast.⁶⁸² Condyloma acuminatum of the nipple and areola has also been described.⁶⁸³ Children occasionally develop lesions, raising the issue of sexual abuse.^{684–689} However, it appears that HPV carriage is not uncommon in prepubertal girls, particularly if they have lichen sclerosis.⁶⁹⁰ Condylomas in children regress spontaneously in more than 50% of cases.⁶⁹¹ This appears to result from a cell-mediated immune response⁶⁹² involving CD8⁺ cytotoxic T lymphocytes.⁶⁹³ The virus attempts to evade immune recognition by downregulating MHC I surface expression.⁶⁹³ Condylomas in all age groups are recurrent in up to one-third of cases.⁶⁹⁴ This may be related to the persistence of HPV DNA in the dermis, on hairs,⁶⁵¹ or in underlying hair follicles.^{695,696} Although malignant transformation of condylomas of the anogenital region is rare, it is more common than in other types of warts, with the exception of epidermodysplasia verruciformis.⁶⁹⁷ MUC-4, a mucin protein encoded by the *MUC4* gene, is thought to play a role in cancer progression; this protein has been found to be strongly expressed – and therefore possibly upregulated – in vulvar condylomas as well as cutaneous squamous cell carcinomas.⁶⁹⁸ Giant condyloma acuminatum of Buschke–Lowenstein is now regarded as a variant of verrucous carcinoma,^{699–702} although this is still disputed by some.⁷⁰³ Regression of a deeply infiltrating variant has been reported following long-term intralesional IFN- α therapy.⁷⁰⁴ Radical surgery has been practiced in some cases.⁷⁰⁵

Because only small amounts of virus are present, characterization of the etiological subtype of HPV involved in the causation of condylomas was made only in the past two decades. HPV-6 and -11 are most commonly identified, but other types have been implicated, including HPV-2, -6, -11, -16, -18, -31, -33, -35, -39, -41–45, -51, -56, and -59.^{492,509,667,706–708} More than one HPV type may be present.⁷⁰⁹ In one study, 83% of cases were positive for HPV-6 and/or -11, whereas 6% were positive for type 16.⁴⁹² HPV-16 and -18 and numerous other uncommon subtypes have oncogenic properties and are sometimes isolated from condylomas, although more usually HPV-16 is seen in association with bowenoid papulosis.⁷¹⁰ HPV oncogenesis is complex and involves genetic susceptibility, immune responses, and environmental and infectious cofactors.⁷¹¹ The concurrence of condyloma

acuminatum and bowenoid papulosis, and of condyloma acuminatum, HPV-31-positive Bowen's disease, and coexisting extramammary Paget's disease,^{712,713} has been reported.^{712,714} Penile lesions, often subclinical, are frequently found in the sexual partners of women with CIN, indicating that the male sexual partners of women with CIN might constitute a reservoir for high-risk HPV.⁷¹⁵

Conventional therapies for condyloma acuminatum include electrodesiccation, cryotherapy, trichloroacetic acid, and podophyllotoxin and related substances.⁶⁸⁹ Phototherapy following the topical application of 5-aminolevulinic acid may be a more effective and safer treatment with a lower recurrence rate compared with CO₂ laser therapy. Refractory cases have been successfully treated with 5% imiquimod cream.^{716,717} Green tea catechins exert antiviral activity, and extracts of these have been used therapeutically.⁷¹⁸ The introduction of a vaccine for certain strains of HPV holds promise for the future; the clinical trials gave impressive results.^{384,719}

Histopathology⁵⁰⁸

There is marked acanthosis, with some papillomatosis and hyperkeratosis. Vacuolization of granular cells is not as prominent as in other varieties of warts, although there are usually some vacuolated koilocytes in the upper malpighian layer (Fig. 26.22). Lesions resembling seborrheic keratoses may be seen; they usually contain human papillomavirus.⁷²⁰ Small penile lesions may only show a slightly thickened granular layer.⁷²¹ Coarse keratohyaline granules may also be present. Langerhans cells are sometimes prominent.⁷²² Acantholysis has been reported in one case.⁶⁸²

If the lesions are treated with podophyllum resin (podophyllin) approximately 48 hours prior to removal, there are striking histological changes. These include pallor of the epidermis, numerous degenerate keratinocytes in the lower half of the epidermis, and a marked increase in this region in the number of mitotic figures.⁷²³ Persistent lesions, resistant to treatment with the immune-response modifier imiquimod, have only rare factor XIIIa-positive dendrocytes in the upper dermis.⁷²⁴ This feature may be responsible for low cytokine production and explain the resistance to treatment.

Papillomavirus common antigen can be detected in approximately 60% of lesions by immunoperoxidase techniques.⁷²⁵ Its presence correlates with that of coarse keratohyaline granules and koilocytes.⁷²⁵

Figure 26.22 Condyloma acuminatum. There are marked acanthosis and lobulated papillomatosis. Vacuolated koilocytes can be focally identified in the upper malpighian layer. (H&E)

More sophisticated techniques increase this detection rate to almost 100%. The presence of MIB-1 (Ki-67) immunostaining in the nuclei of the upper two-thirds of the epidermis correlates with the presence of HPV in lesions in which the morphology is suggestive, but not diagnostic, of condyloma.⁷²⁶

Langerhans cells in condyloma acuminatum show degenerative changes suggesting that they are functionally impaired.⁷²⁷ They are also reduced in number.

FOCAL EPITHELIAL HYPERPLASIA

Also known as Heck's disease, focal epithelial hyperplasia (OMIM 229045) is characterized by multiple soft pink or white papules and confluent plaques, particularly on the mucosa of the lips and cheeks.⁷²⁸ There is a high incidence among Inuits (Eskimos) and American Indians, but there are isolated reports of involvement in other races.^{729,730} Individuals with the HLA-DR allele HLA-DR4 (DRB1*0404) are at risk for the development of this disease.⁷³¹ Familial aggregation has been recorded. HPV-13 and -32 have been implicated in the etiology of this condition.^{510,731-734} HPV-11 has also been reported.⁷³⁵

For HPV infections at other sites, various treatments have been used, including simple excision, electrocauterization, cryotherapy, and curettage. For more widespread lesions, acitretin, etretinate, interferon, methotrexate, and CO₂ laser therapy have been used.⁷³⁶

Histopathology

The involved mucosa is hyperplastic, with acanthosis and some clubbing and fusing of rete pegs. This acanthotic epithelium creates an image resembling a 'bronze age ax' (Fig. 26.23).⁷³⁷ There is a characteristic pallor of epidermal cells, particularly in the upper layers.⁷³⁸ There are often binucleate cells, but inclusion bodies are not found. Among the vacuolated cells are degenerated nuclei resembling mitoses, known as 'mitosoid bodies'.⁷³⁹

BOWENOID PAPULOSIS

Bowenoid papulosis is the presence, usually on the genitalia, of solitary or multiple verruca-like papules or plaques having a close histological resemblance to Bowen's disease.^{740,741} It has a predilection for sexually active young adults. If children develop lesions, the possibility of child

Figure 26.23 Focal epithelial hyperplasia (Heck's disease). Note the broad acanthosis with clubbing and fusing of the rete pegs, creating the image of a 'bronze age ax'. (H&E)

sexual abuse should be considered.⁷⁴² In males, it tends to involve the glans penis and also the foreskin, whereas in females the vulval lesions are often bilateral and pigmented.⁷⁴³ This condition was first described as multicentric pigmented Bowen's disease,⁷⁴⁴ and several other terms were used before acceptance of the term 'bowenoid papulosis'.⁷⁴⁵ Although increasing in incidence, it is still a relatively uncommon condition. Cases localized to extragenital sites such as the neck,^{746,747} face,⁷⁴⁸ and fingers⁷⁴⁹ have been reported. A patient with genital bowenoid papulosis subsequently developed periungual Bowen's disease, both induced by the same HPV types.⁷⁵⁰

Lesions are often resistant to treatment and may have a protracted course, particularly in those with depressed immunity.⁷⁵¹ Spontaneous regression is uncommon. Sometimes there is a history of a previous condyloma. In a small number of cases, invasive carcinoma develops. This risk is greatest in women older than the age of 40 years,^{743,752} but men are not immune.^{753,754} It has been suggested that a cocarcinogenic factor, as yet undetected, may be implicated in this malignant transformation.⁷⁵⁵ Most cases of bowenoid papulosis are due to high-risk HPV-16, but in a small number, HPV-18, -31, -33, -35, -39, and -53, or mixed infections, have been present.^{753,756-760} HPV-67 was detected in a recent case,⁷⁶¹ and there has been a report of periungual bowenoid papulosis associated with HPV-42.⁷⁶² The HPV-16 strain has also been implicated in the pathogenesis of vulval carcinomas and cervical intraepithelial neoplasia.^{763,764} The latter condition is occasionally present in the sexual partner of patients with bowenoid papulosis of the penis.⁷⁴³ The viral oncoproteins E6 and E7 contribute to oncogenesis in multiple ways. They also modulate the expression of p16 and human telomerase reverse transcriptase (hTERT).⁷⁶⁵

Anogenital cancers have been associated not only with the HPV types already mentioned but also with some of the more recently identified types, such as HPV-30, -31, -33, -45, -51, -52, -56, -58, -66, and -69.⁴⁹³

Treatment of bowenoid papulosis usually involves locally destructive or ablative therapies such as surgical excision, shave excision, electrocoagulation, cryotherapy, and 5-fluorouracil. Imiquimod has also been used successfully.^{766,767} It remains to be determined by how much the new vaccine for HPV reduces the incidence of this disease.

Histopathology

The histological differentiation of bowenoid papulosis and Bowen's disease is difficult, and it may be impossible. Bowenoid papulosis is characterized by full-thickness epidermal atypia and loss of architecture. The basement membrane is intact. Mitoses are frequent, sometimes with abnormal forms. They are often in metaphase. Dyskeratotic cells are also present. True koilocytes are uncommon,⁷⁶⁸ although partly vacuolated cells with a 'koilocytotic aura' are sometimes present (Fig. 26.24). The stratum corneum and granular cell layer often contain small inclusion-like bodies that are deeply basophilic, rounded, and sometimes surrounded by a halo. These bodies, together with the numerous metaphase mitoses, are the features that suggest a diagnosis of bowenoid papulosis rather than Bowen's disease.

The dermis usually contains a mild, superficial infiltrate of lymphocytes, often with perivascular accentuation. Patchy interface changes are sometimes present. Amyloid has also been reported in the papillary dermis.⁷⁶⁹

Bowenoid papulosis is commonly classified by gynecological pathologists as vulvar intraepithelial neoplasia (VIN) III.⁷⁵²

Differential diagnosis of infections due to human papillomaviruses

Verruca vulgaris lesions must be distinguished from other acanthotic or papillomatous lesions, including irritated seborrheic keratoses or

Figure 26.24 Bowenoid papulosis. There are atypical keratinocytes throughout the full thickness of the epidermis with several mitoses in metaphase. Small basophilic inclusions are present in the granular layer. (H&E)

prurigo nodularis. Because not all verrucae have apparent viroplastic changes, differentiation from these other entities can be extremely difficult, especially when lesions have been irritated and have significant scale-crusting. Inbowing of epithelial margins or elongated, finger-like papillomatous spires with overlying parakeratotic columns and foci of hemorrhage tend to favor verruca, whereas horn cyst formation and close-set basaloid keratinocytes are more in keeping with seborrheic keratosis, and irregular downgrowths of rete ridges and vertical streaking of papillary dermal collagen are more often seen in prurigo nodularis. However, occasionally, differentiation among these lesions can be almost impossible. Verrucae can sometimes be difficult to distinguish from epidermolytic hyperkeratosis, which can mimic both verruca plana and (in the form of epidermolytic acanthoma) condyloma acuminatum.⁷⁷⁰ Both lesions display vacuolization involving the granular cell layer, but forms of epidermolytic hyperkeratosis also tend to show more extensive vacuolization that reaches into lower levels of the epidermis and is associated with clumped keratohyaline granules. The basophilic cells with pyknotic nuclei seen in epidermodysplasia verruciformis lesions are rather distinctive and allow recognition of this HPV variant; occasionally, this change is seen in the setting of Bowen disease (squamous cell carcinoma *in situ*), one clue suggesting that the epithelial atypia likely developed due to an oncogenic HPV type.

A high percentage of lesions with the features of seborrheic keratoses in the genital region prove to be HPV infection when using PCR methods.⁷⁷¹ Exuberant or otherwise nontypical pearly penile papules (lesions in the angiofibroma family) can be difficult to distinguish clinically from condylomata acuminata. Microscopic differentiation is generally not difficult because the epidermis of pearly penile papules tends to be within normal limits, whereas condylomata feature hyperkeratosis, acanthosis, and often focal koilocytic change. These two conditions can also be distinguished by dermoscopy. Using this method, pearly penile papules consist of uniform, small whitish-pink papules with delicate centrally located vessels, whereas condylomata show irregular papillomatous projections outlined by a peripheral whitish band and with central dotted vessels.⁷⁷²

Regarding bowenoid papulosis, in contrast to typical Bowen's disease, follicular infundibula are usually spared, whereas intraepidermal portions of eccrine sweat ducts tend to be involved. In one study, expression of the tumor suppressor protein p16 was significantly higher in lesions of genital, extragenital, and arsenic-induced Bowen's

disease than in bowenoid papulosis.⁷⁷³ Another recent study showed that p16 is expressed in both condyloma acuminatum and bowenoid papulosis, but staining is focal or sporadic in condyloma acuminatum and strongly, diffusely positive (involving the full thickness of epidermis) in bowenoid papulosis.⁷⁷⁴ Band-like lymphoplasmacytic infiltrates are often present. Some of these findings are also observed after treatment of genital warts with podophyllin; however, epithelial changes resulting from that therapy are markedly diminished 72 hours after application.⁷⁷⁵

PARVOVIRIDAE

The Parvoviridae are single-stranded DNA viruses and among the smallest known DNA-containing viruses to infect mammalian cells. Parvovirus B19, which belongs to the genus *Erythrovirus*, is the only known human pathogen in this family.

PARVOVIRUS B19

Parvovirus infection occurs mainly in school-aged children and teenagers. Approximately 80% of the community is immune to the virus by the age of 50 years.⁷⁷⁶ It can produce an influenza-like illness, miscarriages, fetal hydrops, neonatal angioedema,⁷⁷⁷ polyarthritides, aplastic crises, pure red cell aplasia,⁷⁷⁸ purpura, a generalized petechial eruption,⁷⁷⁹ a petechial rash of the lower extremities,⁷⁸⁰ a 'bathing trunk' exanthem,⁷⁸¹⁻⁷⁸³ vasculitis,⁷⁸⁴ erythema multiforme,⁷⁸⁵ follicular purpuric papules with a baboon syndrome-like distribution,⁷⁸⁶ dermatomyositis,⁷⁸⁷ a Sweet's syndrome-like eruption,⁷⁸⁷ lupus erythematosus-like syndromes,^{785,787} an asymptomatic papular eruption, livedo reticularis,⁷⁸⁸ cutaneous necrosis,⁷⁸⁹ acral pruritus,⁷⁹⁰ the papular-purpuric (petechial) 'gloves-and-socks' syndrome,⁷⁹¹ and erythema infectiosum (fifth disease).⁷⁹²⁻⁷⁹⁶ A Degos-like presentation has been reported; it resulted from an underlying endothelialitis.⁷⁹⁷ There is an increased prevalence of viral DNA in systemic sclerosis skin.⁷⁹⁸

The papular-purpuric 'gloves-and-socks' syndrome is a self-limited infection characterized by pruritic, erythematous papules with petechiae and edema involving predominantly the hands and feet.⁷⁹⁹ Fever, arthralgias, and oral lesions may be present. Lymphangitis is a rare manifestation.⁸⁰⁰ This exanthem usually occurs in adults, but childhood cases have been recorded.^{801,802} It may represent a nonspecific manifestation of several viral infections.⁸⁰³ Although parvovirus B19 has been implicated most often, there are reports of a similar illness following measles virus, Epstein-Barr virus, HHV-6, HHV-7, hepatitis B infection,⁸⁰⁴ coxsackievirus B6, and cytomegalovirus.^{805,806} The simultaneous occurrence of parvovirus B19 and HHV-7 has been reported in a familial setting.⁸⁰² A mother and daughter have also been involved.⁸⁰⁷ In immunocompromised patients, persistent skin lesions and anemia often develop.⁸⁰⁸ Serological confirmation can be used to confirm the diagnosis.⁸⁰⁹ Approximately 50% of the adult population is immune.⁸¹⁰ It should not be confused with the purple glove syndrome resulting from the intravenous injection of phenytoin into a small vein on the dorsal hand.⁸¹¹

Erythema infectiosum (fifth disease or 'slapped-cheek' disease) is an exanthem that may be difficult to distinguish from rubella.⁸¹² A distinctive well-margined rash often appears on the cheeks a few days after the onset of prodromal symptoms. The rash usually becomes more generalized after a few days.

Parvovirus B19 is spread by a respiratory droplet and has an incubation period of 5–14 days.⁸¹⁰ The receptor for the virus is the erythrocyte P antigen, which is also expressed on endothelial cells. The virus has been demonstrated in endothelial cells in lesional skin by several methods, including PCR.^{813,814} It has also been identified in

keratinocytes.⁸¹⁵ Parvovirus B19 has been reported as producing four distinct clinical presentations in one family.⁸¹⁰ This suggests that the immunological response to the virus may play a role in determining the clinical presentation.⁸¹⁶ Parvovirus B19 DNA can be detected in skin of patients with pityriasis lichenoides, in lesions unrelated to B19 infection, and in healthy controls, suggesting viral persistence after primary infection.⁸¹⁷

Because infection in healthy children and adults is self-limited, no specific therapy is warranted.⁷⁷⁶ It should be remembered that parenteral transmission of the disease can occur via the transfusion of blood products from blood donated during the viremic stage of the illness.⁷⁷⁶

Histopathology^{813,814,816}

The changes resemble other viral infections with a mild, usually tight perivascular infiltrate of lymphocytes, mild exocytosis of lymphocytes, and mild basal vacuolar change with occasional apoptotic keratinocytes, giving a so-called interface dermatitis.⁸¹⁸ Extravasation of red cells is often present. Occasionally, the appearances are those of a lichenoid lymphocytic vasculitis (see p. 718), but fibrin is rarely present.⁸¹⁹ Eosinophils and occasional neutrophils may be present. Interstitial lymphocytes and histiocytes have been described, resembling incomplete granuloma annulare,⁷⁸⁷ but this may be a late manifestation of a previous lymphocytic vasculitis in which a hypercellular interstitium ('busy' dermis) and mucin may be present. Perineuritis was also present in a patient with the papular-purpuric gloves-and-socks syndrome associated with mononeuritis multiplex.⁸¹⁹ A recent case of purpuric gloves-and-socks syndrome showed acanthosis with necrotic keratinocytes, intraepidermal vesiculation, subepidermal edema, and an infiltrate consisting of mixtures of leukocytes with leukocytoclasia and erythrocyte extravasation.⁸²⁰ Another case showed evidence for leukocytoclastic vasculitis involving small dermal venules.⁸²¹ Parvovirus B19 has been identified in three cases of purpuric gloves-and-socks syndrome using immunohistochemistry with polyclonal rabbit anti-PVB19 directed toward PVB19 VP2 structural protein.⁸²²

PICORNAVIRIDAE

The Picornaviridae are an important family of RNA viruses that includes the poliovirus, the coxsackievirus, and ECHOvirus. The latter two viruses are now the most common cause of exanthems in children.¹ Most of the cutaneous manifestations are transient macular or maculopapular lesions in the course of an obvious viral illness, and biopsies are rarely taken. As a result, very little is known of the histology. Urticarial and vesicular lesions have also been reported.⁸²³ The most important of the vesicular group is so-called 'hand, foot, and mouth disease', caused mostly by coxsackievirus A16. This virus has also been associated with an eruption resembling that of the Gianotti-Crosti syndrome,⁸²⁴ although this condition is usually associated with hepatitis B infection (see later).⁸²⁵

HAND, FOOT, AND MOUTH DISEASE

Most cases are caused by coxsackievirus A16, although other types have also been implicated. Cases associated with epidemics of enterovirus 71 may develop serious systemic complications.⁸²⁶ The disease is a febrile illness characterized by vesicles in the anterior parts of the mouth and on the hands and feet.⁸²⁷ A case without oral lesions has been reported.⁸²⁶ The vesicles are usually small, and they may be sparse. A relationship between onychomadesis (periodic shedding of the nails from the proximal end) and hand, foot, and mouth

disease has been proposed on a number of occasions.^{828,829} There is also evidence that this nail change preferentially develops where there have been severe cutaneous lesions of hand, foot, and mouth disease.⁸³⁰

Acyclovir has been used to treat patients with this condition, but because enteroviruses lack thymidine kinase, this agent is not suitable for cases with this etiology. Pleconaril, which has specific action on the viral capsid of enteroviruses, may prove to be effective.⁸²⁶

Histopathology

There are intraepidermal vesicles with prominent reticular degeneration and sometimes a few ballooned cells in the base. There are no multinucleate cells or inclusion bodies. Similar changes, usually without ballooning, are seen in the vesicular lesions of other viruses in this family. There is sometimes the additional feature of papillary dermal edema and a mild perivascular inflammatory infiltrate.

TOGAVIRIDAE

The family Togaviridae includes the alphaviruses, formerly known as group A arboviruses. This group includes three mosquito-borne equine encephalitis viruses as well as several so-called 'Old World' species, such as chikungunya, o'nyong-nyong, Sindbis, Ross River, and Barmah Forest. Rubella (German measles) also belongs to this family, but because it is serologically distinct from the alphaviruses and requires no vector for its transmission, it has been placed in the genus *Rubivirus*.

Rubella produces an exanthematous eruption, but it is best known for its causation of the congenital rubella syndrome that results from infection early in pregnancy. Since the introduction of a live-attenuated rubella vaccine in 1969, no large rubella epidemics have occurred in countries where the vaccine is widely used and the congenital rubella syndrome has virtually disappeared.

The alphaviruses tend to present with fever, arthralgia, some myalgia, and skin rashes, but the latter may be very mild and transient. Some variability in presentation occurs, as illustrated by the report from south India that reviewed the cutaneous manifestations of 145 patients with chikungunya fever,⁸³¹ a disease that has recently increased dramatically in incidence and geographic extent.⁸³² A maculopapular eruption was present in one-third of patients. In a recent review, the cutaneous manifestations of this condition, in descending order of frequency, were erythematous macules; maculopapular lesions; vesicles and bullae; desquamation; toxic epidermal necrolysis-like; papular, urticarial, or purpuric; eruption in a photodistribution; vasculitic, acrocyanotic, or acquired ichthyosis; and erythema multiforme-like.⁸³³ Other findings have included pigmentation, which often appeared *de novo*, intertriginous aphthous-like lesions,⁸³¹ and either exacerbation of psoriasis or an eruption resembling guttate psoriasis.⁸³⁴ Cutaneous ulcers may also occur in this condition.⁸³⁵ A tight superficial perivascular infiltrate of lymphocytes is usually present; a focal mild lichenoid reaction is occasionally seen as well.⁸³¹ Both intraepidermal and subepidermal separation have been seen in vesiculobullous lesions.⁸³³ Viperin, an antiviral host protein encoded by the *RSAD2* gene, is believed to play a role in controlling chikungunya viral infection.⁸³⁶

Experimentally, Langerhans cells migrate from the skin to local lymph nodes following cutaneous infection.⁸³⁷ This migration appears to be important in the development of an immune reaction to the virus. Large, atypical lymphoid cells have been reported in a perifollicular lymphohistiocytic infiltrate in a papular eruption in a patient with Sindbis infection.⁸³⁸

Brief mention is made of Ross River and Barmah Forest viruses. Although limited in their extent to Australia and Oceania, the author

has had some experience with them. They serve as a prototype for the other Togaviridae.

ROSS RIVER/BARMAH FOREST VIRUSES

The Ross River and Barmah Forest viruses are alphaviruses of the family Togaviridae. The Ross River virus was isolated by Doherty and colleagues from the mosquito *Aedes vigilax* trapped along the Ross River in northern Queensland, whereas the Barmah Forest virus was isolated from the mosquitoes in the Barmah Forest in northern Victoria, Australia, in 1974.⁸³⁹ Although found mostly in Australia, the Ross River virus has caused major epidemics in Fiji and Samoa.⁸³⁹ Ross River viral infections are nearly three times as common as those due to Barmah Forest virus, but the latter is increasing in incidence.⁸⁴⁰ Climate change is predicted to cause an increase not only in these viral infections but also in infections by some of the other alphaviruses.

After an incubation period of 7–9 days, the presenting symptoms are joint pains, fever, and a rash.^{841,842} Sometimes the polyarthritides is debilitating. Myalgia and fever may persist for 6 months.⁸³⁹ The skin rash is a diffuse maculopapular erythematous eruption that is seen predominantly on the limbs and trunk. It lasts for several days. A rash is more common with Barmah Forest virus.^{839,843}

Histopathology

As with most viral infections, few reports have described the cutaneous findings in these two diseases. Some cases have exhibited a mild, but tight, superficial perivascular infiltrate of lymphocytes and also macrophages; eosinophils may also be present in Barmah Forest viral infections (personal observations). There may be mild perivascular edema and some red cell extravasation in purpuric lesions.⁸⁴² A lichenoid lymphocytic vasculitis is another manifestation of these diseases, but whether it is correlated with persistence of the virus is currently unknown (Fig. 26.25).

FLAVIVIRIDAE

The family Flaviviridae contains three antigenically distinct genera: *Flavivirus*, *Pestivirus*, and *Hepacivirus*. The genus *Flavivirus* contains 30 human pathogens, including the viruses that cause yellow fever, West Nile fever/encephalitis,⁸⁴⁴ St. Louis encephalitis, Japanese encephalitis, and dengue hemorrhagic fever. The *Pestivirus* genus is not of human importance, whereas the genus *Hepacivirus* contains the organism that causes hepatitis C. The public health burden of several flaviviral infections has been such that attention was given many years ago to the development of vaccines to control the diseases. Where available, they have led to a significant decrease in the incidence of that disease. There are four serotypes of the dengue virus, making the development of a vaccine difficult. Furthermore, immunity against one serotype can lead to more serious disease should infection subsequently occur with another serotype.

The following diseases are considered in the account that follows:

- West Nile fever/encephalitis
- Dengue fever
- Hepatitis C.

WEST NILE FEVER/ENCEPHALITIS

West Nile virus is endemic in East Africa, but it first appeared in North America (New York City) in 1999. It has spread steadily throughout the country since that time.⁵ There were 244 deaths in the United

Figure 26.25 Barmah Forest virus infection. (A) There is a lichenoid lymphocytic vasculitis with an unusual amount of subepidermal edema. (B) Rare eosinophils are in the tight perivascular infiltrate. (H&E)

States for the year 2003.⁸⁴⁵ The main reservoir for the virus is birds of the crow family. It is transmitted by culicine mosquitoes.⁸⁴⁶ Cases are now being seen in Europe, Asia and, very rarely, Australia (from the Kunjin subtype).

Approximately 80% of persons infected with West Nile virus have no signs or symptoms.⁵ Only a small number, estimated to be 1 in 150, develop severe neurological disease, and this occurs mainly in individuals older than 50 years of age. Multifocal chorioretinitis appears to be a specific marker for West Nile virus infection, particularly in patients presenting with a meningoencephalitis.⁸⁴⁷ After an incubation period of 3–14 days, individuals with overt disease will develop a febrile illness of sudden onset, often accompanied by malaise, eye pain, headache, and myalgia.

The rash consists of nonblanching, punctuate, erythematous macules and papules. It occurs predominantly on the extremities, particularly the palms and soles, and spreads centripetally. Some tick-borne diseases can mimic this pattern.^{844,848}

Currently, there is no specific drug treatment or vaccine against this infection.⁸⁴⁶

Histopathology

Few reports have appeared on the histopathological findings of the skin rash. In one case, there was a sparse superficial perivascular infiltrate of lymphocytes – a feature commonly seen in viral exanthems.⁸⁴⁸

DENGUE FEVER

Up to 100 million cases of dengue fever occur annually worldwide, making it one of the most important viral diseases in the world.⁵ The more severe hemorrhagic form affects approximately 250,000 individuals each year.⁸⁴⁹ Dengue fever is endemic in tropical and subtropical regions of Asia and Africa, particularly in Southeast Asia, India, and western Pacific countries.⁸⁵⁰ The disease is spreading to other countries, with 609,000 cases in the Americas in the year 2001.⁵ It is now a common cause of an acute febrile illness in travelers returning from endemic areas.⁸⁵¹ The mosquito, particularly *Aedes aegypti*, which breeds in any urban stagnant water, is both the reservoir and the vector of the disease.

There are at least four serotypes of dengue virus, and once infected with one serotype, lifelong immunity to that serotype develops. Immunity to other serotypes is limited and transient, and if there is subsequent infection with a different serotype, the patient is at risk of developing a more severe clinical subtype of the disease, either dengue hemorrhagic fever (DHF) or dengue shock syndrome (DSS). Viral replication appears to occur in dendritic cells, monocytes, and possibly circulating lymphoid cells.⁸⁵² Reinfection, even by a different serotype, results in the activation of memory T cells with the production of a cascade of inflammatory cytokines.⁸⁵² The exact mechanism by which reinfection with a different serotype of the virus results in damage to liver and lung cells and vascular endothelium is controversial. Antibody-dependent enhancement is one postulated mechanism.⁸⁵²

Three clinical subtypes of the disease occur: dengue fever (DF), DHF, and DSS. Asymptomatic infection also occurs.⁸⁵³ DF is the least severe and the most common.⁸⁵⁴ DHF has hemorrhagic manifestations including hematuria and melena.⁸⁵³ Up to 30% of cases of DHF may progress to the more severe DSS as a consequence of increased vascular permeability leading to hypovolemia.

Clinical features of DF consist of the sudden onset of high fevers, myalgia, retro-orbital pain, severe headaches, and rash. Initially, there is flushing erythema of the face, neck, and chest. This is followed a few days later by a more diffuse, erythematous, maculopapular eruption.⁸⁵¹ It is characterized by spared areas of normal skin within the diffuse erythema.⁸⁵⁴

The diagnosis of DF and its clinical variants can be made serologically, by viral isolation, or by the detection of viral antigens by PCR-based methods.

The prevention of DF rests with protective clothing, mosquito nets, and insect repellents. There is concern that patients vaccinated against one serotype and subsequently infected by another are at risk of developing the severe forms of the disease.⁸⁵⁴ Accordingly, a tetravalent vaccine is required, but research is continuing on its development.⁸⁵⁴

Histopathology

There is usually a mild perivascular infiltrate of lymphocytes in the superficial dermis; some exocytosis of these cells may be present.⁸⁵⁴ There is variable red cell extravasation, particularly in the hemorrhagic form of the disease. The histopathological changes are of no prognostic value in predicting the course of the disease.⁸⁵⁵

HEPATITIS C VIRUS

Hepatitis C virus is an RNA virus, approximately 50 nm in diameter. It belongs to the genus *Hepacivirus* of the family Flaviviridae. Since

its discovery in 1989, the hepatitis C virus has assumed great clinical importance as a cause of chronic hepatitis. Other organs may be involved, usually through immunological mechanisms.^{856–859} Skin disorders have been reported in up to 15% of patients afflicted with this virus. Most of these conditions are discussed in more detail elsewhere. They include the following:

- Vasculitis (mainly cryoglobulin-associated vasculitis or polyarteritis nodosa)⁸⁶⁰
- Pigmented purpuric dermatosis (see p. 263)⁸⁶¹
- Sporadic porphyria cutanea tarda (see p. 577)^{862–864}
- Lichen planus (see p. 39)⁸⁶⁵
- Erythema nodosum (see p. 532)
- Urticaria (see p. 227)⁸⁶⁶
- Erythema multiforme (see p. 56)
- Behçet's syndrome (see p. 252)
- Necrolytic acral erythema (see p. 571)
- Red fingers syndrome⁸⁶⁷
- Symmetric polyarthritis with livedo reticularis⁸⁶⁸
- Pruritus.^{860,869}

There appears to be a high incidence of cutaneous reactions in patients with chronic hepatitis C viral infection treated with the combination of IFN- α and ribavirin.⁸⁷⁰ The eruptions may be eczematous, lichenoid, or nonspecific.⁸⁷¹

PARAMYXOVIRIDAE

This family of RNA viruses includes the following genera: *Rubulavirus* (mumps virus), *Respirovirus* (human parainfluenza virus types 1 and 3), *Morbillivirus* (measles virus), *Pneumovirus* (human respiratory syncytial virus), and several others.

MEASLES

Measles, an acute infection caused by the rubeola virus of the genus *Morbillivirus*, is highly contagious and usually seen in children. The pathogenesis of measles is said to begin with infection of the respiratory epithelium. The virus then spreads to lymph nodes, followed by viremia and infection of other organs including the skin.⁸⁷² Koplik spots are a characteristic feature of measles, and they precede the onset of the more widespread rash. Uncommonly, a follicular rash may occur.⁸⁷² A biopsy from the rash of measles shows epidermal spongiosis and mild vesiculation, with scattered shrunken and degenerate keratinocytes.^{873,874} This latter feature may be prominent in patients with AIDS.⁸⁷⁴ Occasional multinucleate epithelial giant cells may be seen in the upper epidermis and in hair follicles and acrosyringial cells.^{872,875} These changes may be accompanied by eosinophils.⁸⁷⁶

RETROVIRIDAE

The family Retroviridae contains the important genus *Lentivirus* to which both species of human immunodeficiency virus, HIV-1 and HIV-2, belong. HIV-1 is the more virulent of the two species and is responsible for the worldwide AIDS pandemic. HIV-2 is limited to areas of West Africa, although it has appeared in some European countries as a consequence of migration. In the account that follows, the term HIV applies to the more common HIV-1 species.

Human T-cell lymphotropic virus types 1 and 2 (HTLV-1 and HTLV-2) are members of the *Delta* genus of the family Retroviridae.

HTLV-1 is the more important of the two species because the majority of patients with HTLV-2 infection remain asymptomatic.

Both genera originated from primates; they are closely related to simian immunodeficiency virus and simian T-cell lymphotropic virus, respectively.

HUMAN IMMUNODEFICIENCY VIRUS (HIV)

HIV is a retrovirus that infects and destroys CD4⁺ T lymphocytes by apoptosis,⁸⁷⁷ with resulting disturbances in cellular immune function.^{878,879} It also infects cells of the central nervous system, producing dementia and motor disturbances. Lymphadenopathy is another manifestation of HIV infection. AIDS is one manifestation of a variety of disorders caused by infection with this virus. AIDS is found most commonly in male homosexuals, in hemophiliacs who have received infected blood, in intravenous drug users, and in areas of Africa, where heterosexual transmission is important. For example, more than 10% of the population in Cameroon, Africa, are currently living with HIV/AIDS.⁸⁸⁰ According to the 2006 UNAIDS survey, an estimated 38.6 million people worldwide were living with HIV infection or AIDS at the end of 2005.⁸⁸¹ Globally, and in every region, the proportion of women with HIV infection has increased dramatically.⁸⁸² In sub-Saharan Africa, approximately 60% of all cases involve women; in the United States, the proportion of women among newly infected or AIDS diagnoses increased from 15% before 1995 to 26% in 2006.⁸⁸² Genital ulcer disease in women is a potent facilitator of HIV transmission.⁸⁸³ Viremia is lifelong.

Kaposi's sarcoma was the first cutaneous manifestation of AIDS to be reported (see p. 1101). It is found in up to one-third of patients and is an adverse prognostic factor. Its incidence is lower in some non-Western countries, such as India.⁸⁸⁴ The role of HHV-8 in its etiology is discussed elsewhere (see p. 731). Many other cutaneous effects have been described in recent years. These are classified into three broad categories: infections, usually of an opportunistic nature; neoplasms,^{885,886} and non-infectious dermatoses.^{887–898} Malignant melanoma and squamous cell carcinoma are examples of cutaneous malignancies that have a more aggressive course in patients with HIV infection.⁸⁹⁹ Lymphoma is increased in incidence.^{900,901} These diseases are detailed in **Table 26.1**. Detailed references can be found in a number of reviews of this subject.^{899,902–908}

Opportunistic infections, and some cancers,⁹⁰⁹ have decreased in patients with HIV since the introduction in 1997 of HAART, now called simply antiretroviral therapy (ART). This therapy typically consists of 3 or more medications from the current armamentarium of 20 anti-HIV drugs in five separate classes.⁸⁹⁹ Viral titers fall with this therapy, and there is a progressive increase in CD4⁺ cells.⁹¹⁰ Over time, reappearance of the complete T-cell repertoire occurs.⁹¹¹

Other skin conditions that seem to improve or decline in incidence with HAART include Kaposi's sarcoma,⁸⁹⁹ eosinophilic folliculitis, candidiasis, dermatophyte infections, herpes simplex infections, Norwegian scabies, and verrucous lesions of herpes zoster.⁹¹¹ The initiation of HAART may exacerbate herpes zoster,⁹¹⁰ mycobacterial infections,⁹¹² and other granulomatous diseases.⁹¹³ It also increases the odds of developing photosensitivity and increases the incidence of molluscum contagiosum.⁹¹⁰ Such diseases are part of the spectrum of the so-called immune reconstitution syndrome.⁹¹³ Complications of HAART, using protease inhibitors, include a lipodystrophy (see p. 545) and paronychia.⁹¹⁴

Early signs of HIV infection may be a roseola-like rash associated with recent infection and seroconversion,^{915–918} or the development of psoriasis/seborrheic dermatitis,⁹¹⁹ pruritic lesions,^{920,921} herpes simplex and zoster, a chronic acneiform folliculitis, oral candidosis, tinea, or impetigo of the neck and beard region.^{922–924} Seborrheic dermatitis,

Table 26.1 Cutaneous manifestations of AIDS

Infections

Viral: molluscum contagiosum, herpes simplex, herpes zoster, verruca vulgaris, condylomas, cytomegalovirus, oral hairy leukoplakia, Kaposi's sarcoma

Bacterial: mycobacterial infections, more usual bacterial infections, bacillary angiomatosis

Spirochetal: syphilis

Fungal: candidosis, dermatophytosis, histoplasmosis, cryptococcosis, tinea versicolor, phaeoconchyphomycosis, nocardiosis, mucormycosis, *Penicillium marneffei* infection

Protozoa: acanthamebiasis, pneumocystosis

Arthropod: scabies, demodicosis

Neoplasms

Kaposi's sarcoma, cutaneous lymphomas, Bowen's disease, squamous and basal cell carcinomas, cutaneous melanomas

Dermatoses

Psoriasis, seborrheic dermatitis, pityriasis rubra pilaris, acquired ichthyosis, asteatosis, porokeratosis, vasculitis, folliculitis, contact dermatitis, photosensitivity, vitiligo, yellow nail syndrome, papular eruption, idiopathic pruritus, a chronic diffuse dermatitis, severe drug reactions, alopecia, palmoplantar keratoderma, porphyria cutanea tarda, acrodermatitis enteropathica, neutrophilic eccrine hidradenitis

photosensitivity, and xerosis are three of the more persistent cutaneous manifestations.^{925,926} The incidence and severity of skin disease is a good indicator of the underlying immune status of the patient.^{927,928} Pregnancy does not seem to increase the prevalence of cutaneous diseases in patients with HIV infection.⁹²⁹ Infections in immunocompromised patients may differ in severity and other clinical features from those in normal hosts.^{930–932}

A unique manifestation of HIV infection is oral 'hairy' leukoplakia, which is characterized by raised, poorly demarcated projections on the lateral borders of the tongue, resulting in a corrugated or 'hairy' surface.^{933–935} It has been observed in nearly 25% of patients with HIV-associated skin disorders.^{906,936} It is induced by Epstein-Barr virus, but human papillomavirus has also been identified in some biopsy specimens.⁹³⁷ *Candida* is frequently present. The development of OHL in patients with HIV infection indicates advanced immunosuppression.⁹³⁶ In other clinical settings of immunosuppression, however, OHL is quite rare.

Pruritic papular eruption is the most common cutaneous manifestation in HIV-infected patients in most series.^{938–940} It consists of chronic, pruritic, discrete papules on the trunk, extremities, and face.⁹⁴¹ Excoriation is often present. The incidence is increased in patients with low CD4 cell counts.⁹⁴⁰ This eruption is distinct from the rare widespread, pruritic disorder, often with pigment changes, seen in late-stage HIV infection and characterized by atypical lymphocytes in the skin, which are CD8⁺. This pseudo-Sézary syndrome rarely progresses to frank lymphoma.⁹⁴² Pruritic papular eruption also needs to be distinguished from follicular eruptions, which are also increased in HIV-infected individuals.⁹⁴¹

Changes in the immune system, including T-cell function, antigen response, and shifting cytokine expression, as well as a propensity for autoimmune reactions, appear to underlie the skin changes occurring in AIDS.^{943,944} Their occurrence correlates with low CD4 lymphocyte counts.^{945–948} Cutaneous infections and a pruritic eruption have been reported in association with a 'syndrome' characterized by idiopathic CD4⁺ lymphocytopenia but no evidence of HIV infection.^{949–951}

Histopathology⁹⁴⁴

Various inflammatory dermatoses occur in patients infected with HIV-1. Subtle differences have been found in the expression of the diseases in these patients compared to patients without HIV infection. The number of neutrophils and eosinophils in inflammatory infiltrates may increase during the course of the disease. Plasma cells are sometimes present in diseases in which they are not usually found. Spotty parakeratosis is also more common. Apoptotic keratinocytes, often with an adjacent lymphocyte, are sometimes seen. Occasionally, the appearances resemble those seen in GVHD (see p. 60). T cells, negative for CD7, are increased in cutaneous infiltrates.⁹⁵² This class of lymphocyte is epidermotropic. Increased numbers of CD30⁺ cells appear in the infiltrates of inflammatory dermatoses in later stages of AIDS.⁹⁵³

The *pruritic papular eruption* of HIV infection shows variable features. There is a superficial perivascular infiltrate of lymphocytes, often with some eosinophils. Neutrophils and plasma cells are less common.^{954,955} Extension of the infiltrate around the deep plexus and appendages also occurs. Factor XIIIa-positive cells are usually increased. Dermal fibrosis and changes suggestive of early 'necrobiosis' are often present.

In the *acute exanthem* of HIV infection (seroconversion), there is a tight perivascular infiltrate of lymphocytes. Epidermal changes are usually mild but may include spongiosis, vacuolar alteration, scattered apoptotic keratinocytes, or epidermal necrosis.⁹⁵⁶⁻⁹⁵⁹ Folliculitis is uncommon. In many cases, the changes resemble those seen in other viral exanthems.

In *oral 'hairy' leukoplakia*, there is some acanthosis and parakeratosis. Large pale-staining cells resembling koilocytes are present in the upper stratum malpighii. *Candida* is frequently present in the keratin projections on the surface (see previous section on [Epstein-Barr viral infections](#)).

Differential diagnosis

There has been some confusion regarding the distinction between pruritic papular eruption and eosinophilic folliculitis of HIV disease. In a detailed comparative study, there was no significant difference between the two in terms of perifollicular infiltrates, although eosinophilic folliculitis biopsies seem to have heavier perivascular and diffuse infiltrates.⁹⁶⁰ Crust, hyperkeratosis, acanthosis, and eosinophilic infiltrates were not prominent in either disease, and an eosinophil component of the infiltrate was comparable in the two conditions. Similarly, there were only quantitative rather than qualitative differences in expression of lymphocyte and Langerhans cell markers. The authors concluded that these two conditions may be part of a spectrum of the same disease process.⁹⁶⁰

HUMAN T-LYMPHOTROPIC VIRUS TYPE 1 (HTLV-1)

The human retrovirus HTLV-1 was first isolated in 1980. It is found in areas of Japan, the Caribbean, and sub-Saharan Africa. Immigration has led to its dissemination to other countries, although its seroprevalence in the United States is very low.⁹⁶¹ This virus was originally found to be the cause of adult T-cell leukemia/lymphoma (see p. 1183), but it has been associated with infective dermatitis of children – a condition with close clinical and histopathological similarities to atopic dermatitis.⁹⁶² Both diseases are a chronic dermatitis with a propensity for colonization with *S. aureus* and β -hemolytic streptococci.⁹⁶³ Infective dermatitis presents as an eczema of the scalp, axillae and groins, external ear, and retroauricular region. Dermatopathic lymphadenopathy is common.^{961,963,964} Erythema

multiforme-like and ichthyosis-like lesions have also been reported.^{965,966} Breast-feeding appears to be the origin of the infection in children.⁹⁶² Flower cells were recently found in the peripheral blood of HTLV-1-infected children and adolescents, including a few who had infective dermatitis.⁹⁶⁷ Flower cells – so named because of their petal-shaped nuclei – are typically found in HTLV-1-associated adult T-cell leukemia, and their detection suggests the possibility that those individuals may be at greater risk for developing adult T-cell leukemia/lymphoma.⁹⁶⁷ Another manifestation of HTLV-1 infection is tropical spastic paraparesis/HTLV-1-associated myelopathy (TSP/HAM); infective dermatitis may progress either to leukemia/lymphoma or to TSP/HAM.⁹⁶⁸ In fact, clustering of TSP/HAM and infective dermatitis associated with HTLV-1 has been reported in Salvador, Bahia, Brazil.⁹⁶⁹

HTLV-1 infection can also produce tropical spastic paraparesis and a myelopathy.^{961,970}

Co-infection with HIV is sometimes found. These patients have a higher risk of inflammatory dermatoses than do patients with either disease alone.⁹⁷¹

OTHER VIRAL DISEASES

The diseases that follow are caused by RNA viruses, or presumptive viruses with the exception of hepatitis B, which is caused by a DNA virus of the family Hepadnaviridae. It is considered here so that its description is included with hepatitis A.

Some of the viruses still to be considered have a limited regional localization, and their cutaneous manifestations are of little clinical importance in comparison to the encephalitis that accompanies some of these infections. Several families of RNA viruses are considered briefly in this introduction, including the following:

- Arenaviridae (including Lassa virus)
- Filoviridae (including Ebola virus)
- Bunyaviridae (including hantaviruses)
- Reoviridae (including rotavirus).

The **Arenaviridae** are RNA viruses that cause asymptomatic or mild disease or a more severe clinical illness.⁵ The latter category includes lymphocytic choriomeningitis, the first recognized cause of aseptic meningitis in humans. Other arenaviruses are Lassa virus, Junin virus, Tamiami virus, Machupo virus, and Whitewater Arroyo virus. They cause a hemorrhagic fever with a mortality rate of up to 15%.⁵ Contact with rodent excreta causes human disease. Vaccines for some of these viruses are under development.⁵

The **Filoviridae** are contained in a single genus, *Filovirus*, but it is separated into two genotypes, Marburg and Ebola. Marburg and Ebola viruses both cause severe hemorrhagic fevers.⁵ They are indigenous to Africa. Ebola virus spreads to close contacts; it is particularly likely to spread to health care workers. The cutaneous manifestations include a maculopapular centripetal rash associated with varying degrees of erythema, which desquamates after 5–7 days.⁵ No virus-specific treatment exists.

The **Bunyaviridae** family encompasses approximately 300 different viruses, 2 of which are associated with hemorrhagic fevers and mucocutaneous lesions: Rift Valley fever and Crimean-Congo hemorrhagic fever. Sporadic outbreaks occur in humans. Included in this family is the genus *Hantavirus*, which includes viruses specific to rodent genera worldwide. The virus is transmitted by aerosols of rodent excreta, saliva, and urine. They are listed in the excellent review of this subject by Lupi and Tying.⁵

The family **Reoviridae** includes the genus *Rotavirus*, the most common cause of severe gastroenteritis in children younger than the age of 5 years. The primary mode of transmission is fecal-oral. It has been associated, rarely, with exanthema, Gianotti-Crosti syndrome,

and acute infantile hemorrhagic edema.⁹⁷² This family also contains the orbiviruses, which include the agent of Colorado tick fever in humans.

The remainder of this section includes a discussion of the following diseases:

- Hepatitis A
- Hepatitis B (including Gianotti–Crosti syndrome)
- Kikuchi's disease
- Asymmetric periflexural exanthema.

HEPATITIS A VIRUS

Skin manifestations associated with infection by hepatitis A virus have been rarely reported. They include a photo-accentuated eruption, accompanied by the deposition of IgA in endothelial cells of the upper dermis.⁹⁷³ The Gianotti–Crosti syndrome (see later) and a vasculitis are other rare manifestations.

HEPATITIS B VIRUS

The dermatological manifestations of the hepatitis B virus include the following:

1. A serum sickness-like prodrome with urticarial or vasculitic lesions and, rarely, an erythema multiforme or lichenoid picture⁹⁷⁴
2. A rare, photolocalized pustular eruption⁹⁷⁵
3. Polyarteritis nodosa^{976,977}
4. Essential mixed cryoglobulinemia
5. Oral lichen planus⁹⁷⁸
6. Pitted keratolysis⁹⁷⁸
7. Papular acrodermatitis of childhood (Gianotti–Crosti syndrome).^{825,979,980}

Gianotti–Crosti syndrome

Gianotti–Crosti syndrome is characterized by a nonrelapsing, symmetrical, erythematopapular rash lasting approximately 3 weeks and localized to the face and limbs, with the addition sometimes of lymphadenopathy and acute hepatitis, usually anicteric.^{981–984} Truncal lesions sometimes occur.⁹⁸⁵ It primarily affects children between 2 and 6 years of age.⁹⁸⁴ The syndrome has also been associated with many other viruses, including hepatitis A,⁹⁸⁶ cytomegalovirus,⁹⁸⁷ herpesvirus-1,⁹⁸⁸ herpesvirus-6,⁴⁵⁷ Epstein–Barr virus,^{989,990} adenovirus,⁹⁸⁷ rotavirus,^{972,991} parainfluenza virus,⁹⁹² and coxsackievirus.^{993,994} It has also been reported following various immunizations,^{995–999} including measles–mumps–rubella and diphtheria–tetanus–pertussis¹⁰⁰⁰ and influenza H1N1,¹⁰⁰¹ and also following *Mycoplasma pneumoniae* infection.¹⁰⁰² The histology can show a characteristic mixture of three tissue reactions: spongiotic, lichenoid, and lymphocytic vasculitis. Usually, the lichenoid features consist of mild basal vacuolar change; rarely, this is a dominant feature.¹⁰⁰³ Red cell extravasation and papillary dermal edema are other features.

A recurrent erythematous asymptomatic papular rash on the trunk and proximal extremities has been reported in hepatitis B carriers.¹⁰⁰⁴ Histopathological study showed a superficial and deep perivascular mononuclear infiltrate in the dermis.¹⁰⁰⁴

KIKUCHI'S DISEASE

Kikuchi's disease is a rare self-limiting lymphoproliferative disorder characterized by acute or subacute necrotizing lymphadenitis.¹⁰⁰⁵ It affects predominantly young adult females.¹⁰⁰⁶ It is of presumptive

viral origin, based on its clinical features and course. Most cases have been reported from Japan, but cases from other countries continue to be reported.^{1007,1008} Viruses implicated have included HHV-6, HHV-8,¹⁰⁰⁹ HTLV-1,¹⁰¹⁰ EBV,^{442,443} and cytomegalovirus. However, in a study of archival tissue of 34 cases, HHV-8 and EBV were not detected in any case.¹⁰¹¹ In a more recent study, the HHV-8 genome, but not protein, was detected in a small proportion of cases.¹⁰¹² Cutaneous involvement occurs in approximately 30% of patients. The eruption may be morbilliform, urticarial, maculopular, or disseminated erythema.^{1013,1014} Cervical lymphadenopathy and fever are important clinical features.¹⁰¹⁵ Kikuchi's disease has been reported in association with cutaneous lupus erythematosus^{1016–1019} and Still's disease.¹⁰²⁰ There has been a recent case report of adult Still's disease presenting as lupus erythematosus-like facial erythema associated with Kikuchi's disease.¹⁰²¹ A t(2;16) chromosomal translocation was present in one case.¹⁰⁰⁵ Immediate remission of the disease has followed the use of oral ciprofloxacin.¹⁰²²

Histopathology^{1013,1023,1024}

The histological changes may show some resemblance to lupus erythematosus, with a lichenoid (interface) reaction with basal vacuolar change and some apoptotic keratinocytes. There is a variable superficial and deep perivascular infiltrate of lymphocytes and histiocytes in the dermis. Extension into the subcutis is not uncommon.

Subepidermal edema is often present, and histiocytes containing karyorrhectic nuclear debris are often seen in the base of the edema.¹⁰²⁴ A CD68 stain confirms that many of the cells that initially seem to be lymphocytes are of histiocytic lineage.^{1024,1025} The macrophages express CD68 and CD123; neutrophils are usually absent. The predominant cell type among lymphocytes is the CD8⁺ cytotoxic T cell.¹⁰²⁵ Cells with a cleaved or deformed nucleus, sometimes resembling Reed–Sternberg cells, have been reported; other histiocytic cells have crescent-shaped nuclei.¹⁰²⁶ There is a conspicuous absence of neutrophils and a paucity of plasma cells.¹⁰²⁴ A similar clinical picture can be seen in some adverse antibiotic-induced eruptions associated with EBV infection.¹⁰²⁷

The lymph nodes show paracortical areas of necrosis with abundant karyorrhectic debris.¹⁰²⁵ Numerous histiocytes are present in these areas as well as large lymphoid cells.

Differential diagnosis

Subcutaneous panniculitis-like T-cell lymphoma also has a macrophagic component and a predominance of CD8⁺ cytotoxic T cells, and it can sometimes have lupus erythematosus-like epidermal and dermal changes (vacuolar alteration of the epidermal basilar layer and interstitial dermal mucin deposition). However, Kikuchi's disease lacks the rimming of lipocytes by atypical lymphoid cells.¹⁰²⁵ NK/T-cell lymphomas have different immunohistochemical characteristics (CD56 positivity) and are positive for EBV by *in situ* hybridization. Pityriasis lichenoides acuta has overlapping features with Kikuchi's disease, including vacuolar alteration of the epidermal basilar layer and a wedge-shaped dermal infiltrate, but the former can also have neutrophils and is rarely accompanied by histiocytes.¹⁰²⁵ The resemblance to lupus erythematosus can be troubling, particularly because both diseases have interface changes and dermal mucin deposition. In difficult cases, direct immunofluorescence can be helpful because Kikuchi's disease does not show deposition of immunoglobulins along the epidermal basement membrane zone.¹⁰²⁵

ASYMMETRIC PERIFLEXURAL EXANTHEM

Also known as unilateral laterothoracic exanthem, asymmetric periflexural exanthem is of presumptive viral etiology, although no virus

has yet been consistently detected by various methods.^{1028,1029} Parvovirus B19 has been detected serologically in several cases.^{1030,1031} Sometimes there are upper respiratory tract prodromes.¹⁰³⁰ It begins as a unilateral eruption close to the axilla with centrifugal spread.¹⁰³² It is typically described as a maculopapular scarlatiniform eruption or an eczematous dermatitis.¹⁰³⁰ It may be mildly pruritic. Regional lymphadenopathy is common.¹⁰³³ There is spontaneous resolution after several weeks. This disorder is rare after childhood;^{1034–1036} the youngest patient to be reported was a 4-month-old female infant.¹⁰³³

Histopathology

There is a superficial perivascular infiltrate of lymphocytes that often forms a tight cuff around the vessels. Some authors have described a

lymphocytic infiltrate around eccrine ducts with mild miliarial spongiosis and exocytosis of lymphocytes into the acrosyringium.^{1032,1037} Mild lichenoid changes may be present in late lesions.

INTRODUCTION

The protozoa are single-celled organisms of great medical importance. There are six categories, covering several phyla; not all are of dermatopathological interest:

- Amebae
- Flagellates
- Coccidia
- Microsporidia
- Ciliates
- Sporozoa.

The amebae include the organisms that cause amebiasis and acanthamebiasis. The flagellates constitute an important group that includes the organisms for trypanosomiasis, leishmaniasis, trichomoniasis, and giardiasis. The coccidia include *Toxoplasma gondii* and *Cryptosporidium parvum*; only toxoplasmosis is considered further. The microsporidia and ciliates include a range of intestinal parasites but no organisms of dermatopathological interest. Finally, the sporozoa include *Plasmodium* spp. and *Babesia* spp., responsible for malaria and babesiosis, respectively.¹ *Pneumocystis jiroveci* (formerly *Pneumocystis carinii*) has recently been reclassified as a fungus, but it lacks many of their features. It is considered here by tradition.

Using an indirect immunoperoxidase technique, protozoal and other infectious pathogens have been demonstrated in routinely processed paraffin sections with the use of diluted sera from patients with known antibodies to the suspected disease.² The test has a high sensitivity but low specificity.

AMEBAE

Amebae are single-celled organisms with trophozoite and cyst stages in the life cycle. Their motility results from pseudopods. The important human pathogen within this group is *Entamoeba histolytica*. Other species within this genus are nonpathogenic. In recent years, there has been an increase in disease caused by other amebae, known as free-living amebae – *Acanthamoeba*, *Balamuthia*, and *Naegleria*.³

AMEBIASIS CUTIS

Amebiasis is endemic in areas of Africa, the Asia-Pacific region, and Latin America. Visceral amebiasis is an important cause of morbidity and mortality in these countries.

Cutaneous infection with *E. histolytica* (amebiasis cutis) is quite rare, occurring chiefly in the tropics.⁴⁻⁶ A study of amebiasis cutis from an endemic area in South Africa found 41 patients with cutaneous disease during an 8-year period.⁷ It usually develops as a complication of amebic colitis, producing irregular areas of ulceration with verrucous borders around the anus, sometimes spreading to the thighs and genitalia.⁸⁻¹⁰ The lesions are usually rapidly progressive and painful.³ Cutaneous lesions may also arise by fistulous extension from a gastrointestinal or hepatic abscess, around a colostomy or abdominal wound, or as a consequence of venereal transmission.¹¹ Penile lesions are being seen with increasing frequency in male homosexuals. Cutaneous disease may be the presenting manifestation of undetected visceral amebiasis.⁷ It is also commonly associated with HIV infection, particularly in some areas of the world.⁷ Cutaneous amebiasis is rare in children.¹²

The ulcers are covered by gray slough and have a peculiarly unpleasant smell. Large exophytic lesions resembling squamous cell carcinoma may develop, particularly in genital areas.¹³ These lesions may lead to an erroneous diagnosis of carcinoma, with unnecessary surgery being

carried out. The author has seen two cases of amebiasis of the penis in which amputation of the organ was performed.

Metronidazole has been used to treat cutaneous disease.⁶

Histopathology

Sections usually show an ulcerated lesion with extensive necrosis in the base, pseudoepitheliomatous hyperplasia at the margins, and a nonspecific inflammatory infiltrate extending into the deep dermis and subcutaneous tissues beneath the ulcer base.¹⁴ In the series from South Africa, referred to previously, two fairly distinctive histopathological patterns were observed. Approximately one-third of cases were characterized by superficial lesions with the ulceration and inflammation confined to the upper dermis, whereas the remaining cases had deep lesions extending into subcutis with extensive 'liquefactive' necrosis with karyorrhectic debris, numerous trophozoites, and sometimes suppurative foci.⁷ The deep variant was associated with visceral disease.⁷ Sometimes there is extensive pseudoepitheliomatous hyperplasia involving much of the lesion, with only small punctate areas of ulceration (Fig. 27.1). This may resemble a verrucous carcinoma. *Entamoeba histolytica* may be found, singly and in clusters, in the overlying exudate (Fig. 27.2). They differ from histiocytes by the presence of a single eccentric nucleus with a prominent central karyosome and occasional phagocytosed red blood cells in the cytoplasm.⁹ The term hematophagous amebic trophozoites (HATS) has been used for these amebae.⁷ In sections of fixed tissue, their diameters are usually within the range 12–20 µm, but larger forms up to 50 µm may be seen.³ They are basophilic. Viable amebae can be highlighted in the necrotic debris by the periodic acid–Schiff (PAS) stain. Degenerate amebae are not enhanced by this stain.⁷ Rapid diagnosis is enhanced by a single-tube multiprobe real-time polymerase chain reaction (PCR) technique.¹⁵

ACANTHAMEBIASIS

The free-living amebae of soil and water – *Acanthamoeba*, *Balamuthia*, and *Naegleria* – are facultative parasites of humans.^{16,17} Although meningoencephalitis is the major clinical feature, there have been a number of reports of pustular, chronic ulcerating, nodular, or sporotrichoid lesions in the skin,^{18,19} particularly in patients with AIDS²⁰⁻²⁵ and in organ transplant recipients.^{26,27} *Acanthamoeba* also causes

Figure 27.1 Amebiasis of the penis. This case was misdiagnosed on biopsy as a squamous cell carcinoma because of the marked pseudoepitheliomatous hyperplasia. (H&E)

Figure 27.2 Amebiasis. Organisms are present in the ulcer base. (H&E)

keratitis in persons who use nonsterile contact lens solutions.²⁸ *Balamuthia* infection can produce ulcerated lesions²⁹ or indurated violaceous plaques.³⁰ Trauma can initiate these lesions, and they can occur in apparently immunocompetent individuals. This infection has also been associated with thrombotic amebic angiitis involving especially the central nervous system.^{31,32} Cases of fatal amebic encephalitis caused by *Balamuthia mandrillaris* have been reported.^{29,33} The patients initially presented with an indurated plaque on the face, the biopsy of which was misinterpreted.^{29,33} Deaths from *Balamuthia* infection are common, although there has been a report of successful treatment with miltefosine, fluconazole, and albendazole.³⁰

Histopathology

Sections have shown tuberculoid granulomatous lesions in the deep dermis and subcutaneous tissue, often with accompanying vasculitis.^{18,21} In patients with AIDS, granulomas are not always present. There may be a diffuse neutrophilic infiltrate with numerous organisms, and abscess formation. A suppurative panniculitis has also been described.^{22,23,25} Amebae, 15–40 μm in width, can often be seen lying free in the tissues;³⁴ they may take the form of trophozoites or cysts.²³ Organisms are not invariably present in immunocompetent individuals with granulomas.

Of the two cases of *Balamuthia* that presented with cutaneous lesions, one was misinterpreted by experts from throughout the world,³³ and the other was initially misdiagnosed, although a subsequent biopsy showed a suppurative and granulomatous process with multinucleated giant cells and pseudoepitheliomatous hyperplasia.²⁹ There was extensive tissue necrosis. Amebic trophozoites were identified in the necrotic tissue and in the walls of small blood vessels.²⁹ There may be varying degrees of necrosis, associated with thrombosis and/or vasculitis, together with trophozoites or cysts in vessel walls. The trophozoites show irregular contours, vacuolated cytoplasm, and a clear nucleus with a dense karyosome (Fig. 27.3). Cysts have doubly contoured walls, with an irregular outer wall and a polygonal inner wall. The cyst walls (but not the trophozoites) are positive for Gomori methenamine silver (GMS) stain.

Differential diagnosis

Trophozoites of amoebae can be confused with macrophages, particularly because, like macrophages, they sometimes contain cellular debris. However, macrophages are smaller, and their nuclei are larger and possess coarser chromatin.³⁵

Figure 27.3 Acanthamebiasis. Low-power (A) and high-power (B) views of *Balamuthia mandrillaris* in a cutaneous lesion. These trophozoites feature pseudopods, granular cytoplasm, and nuclei that contain karyosomes. (H&E)

FLAGELLATES

The flagellates are a group of protozoa that move by means of a flagella. They are of considerable medical importance. The following diseases are considered:

- Trypanosomiasis
- Leishmaniasis
- Trichomoniasis
- Giardiasis.

TRYPANOSOMIASIS

African trypanosomiasis is caused by the protozoa *Trypanosoma brucei gambiense* and *Trypanosoma brucei rhodesiense*, which are transmitted by the bite of the tsetse fly (*Glossina* species).^{36,37} The Gambian

variant has increased in incidence in central Africa, with nearly 100,000 new infections each year.³⁷ Although the major clinical manifestations are fever and neurological signs, cutaneous lesions develop in approximately half of the patients.³⁸ These lesions consist of an indurated erythematous 'chancre' at the site of the bite, followed several weeks later by a fleeting erythematous maculopapular rash, often with circinate forms.³⁹ The lesions in this latter secondary stage are known as trypanids.⁴⁰ The diagnosis is made by finding hemoflagellates in thick⁴¹ or thin⁴² peripheral blood smears. Newer diagnostic techniques include PCR, nucleic acid sequence-based amplification (NASBA),⁴² and the Loopamp *Trypanosoma brucei* (LAMP) assay, which is being studied for use under field conditions.⁴³

American trypanosomiasis (Chagas' disease), caused by *T. cruzi*, affects 17 million people in Latin America.⁴⁴ It is transmitted by the bite of the triatomine insect species of the family Reduviidae.⁴⁴ A transient nodule appears at the site of entry of the protozoa.⁴⁵ It causes myocardial disease and intestinal dilatation from damage to the myenteric plexus.⁴⁶ Cutaneous disease is very rare and results from reactivation of latent disease in immunosuppressed patients.⁴⁷ Clinically, it may cause a large indurated plaque, erythematous papules and nodules, panniculitis, and ulcers.⁴⁴

Histopathology

Sections of the chancre show a superficial and deep, predominantly perivascular infiltrate with lymphocytes and many plasma cells, with some resemblance to the lesions of secondary syphilis.³⁸ Organisms can be seen in Giemsa-stained smears taken from the exudate of a chancre, but they are not usually seen in tissue sections.³⁸ In the secondary stage, the trypanids show mild spongiosis with exocytosis of lymphocytes, a superficial perivascular infiltrate of lymphocytes, and a mild diffuse infiltrate of neutrophils with some leukocytoclasia.⁴⁰ Amastigotes of *T. cruzi* may be present in the epidermis, in walls of blood vessels, in arrector pili muscles, and in the cytoplasm of inflammatory cells in cutaneous lesions of Chagas' disease. A variable inflammatory cell infiltrate is also present.

LEISHMANIASIS

Leishmaniasis is an important protozoal infection, with an estimated 1–2 million new cases occurring worldwide each year.^{48–52} Its incidence is increasing, although public health measures in some provinces have led to a decline in those areas.^{53–55} Armed operations in Afghanistan and Iraq have given rise to a significant number of cases in troops stationed there.^{56–60} It is also being seen increasingly in travelers^{61–64} and refugees.^{65,66} It has also been reported in a person in the United Kingdom who had no history of recent travel to an endemic area.⁶⁷ A similar case has been reported from Taiwan, a non-endemic country.⁶⁸ Leishmaniasis can be classified into three types, each caused by a different species of *Leishmania*:

1. Cutaneous (oriental) leishmaniasis caused by *L. tropica* in Asia and Africa and by *L. mexicana* in Central and South America⁶⁹
2. Mucocutaneous (American) leishmaniasis caused by *L. braziliensis*
3. Visceral leishmaniasis (kala-azar) caused by *L. donovani*.

This classification is an oversimplification because a great deal of clinical overlap exists between the various forms.^{70,71} For example, visceral infection, caused by *L. tropica*, was reported in American soldiers infected in Saudi Arabia during operation 'Desert Storm'.^{72,73} A newer classification of cutaneous leishmaniasis has been proposed.⁵¹ The diagnosis can be made by identifying parasites on histological section⁷⁴ or in smears,⁷⁵ by culture on specialized media, by the leishmanin intradermal skin test (Montenegro test), by fluorescent antibody tests using the patient's serum,⁷⁶ or by PCR using species-specific primers.⁷⁷ Results of PCR can be falsely positive.⁷⁸ The leishmanin test is usually

negative in the forms with cell-mediated hyporeactivity, such as the diffuse cutaneous forms and the visceral form (kala-azar).⁷²

Various subspecies of *Leishmania* have been documented in recent years (see later).⁷² At least 20 species infect humans. Genomic analysis of several species has shown that genes that are differentially distributed between the species encode proteins implicated in host–pathogen interactions and parasite survival in the macrophage.⁵²

In recent years, attention has focused on the role of the immune system and other mechanisms in the elimination of *Leishmania*.^{79,80} Nitric oxide, inducible nitric oxide synthase (iNOS), interleukin-12 (IL-12), and interferon (IFN- γ) also play a role.^{81–83}

Cutaneous leishmaniasis

Cutaneous leishmaniasis, a chronic self-limited granulomatous disease of the skin, is usually caused by *L. tropica*. It is common in children.⁵¹ It is endemic in the Middle East, around the eastern Mediterranean, in North Africa, and in areas of Asia.^{73,84–91} The term 'Old World' leishmaniasis has been used for such cases. Subspecies of *L. tropica* include *L. major*, *L. minor*, and *L. aethiopica*.^{72,92,93} Sandflies of the genus *Phlebotomus* are the usual vectors. The incubation period following the sandfly bite is weeks to months and depends on the size of the inoculum.⁹⁴ In Central and South America, and in areas of Texas ('New World'), *L. mexicana* is the species involved.^{95–97} Subspecies include *L. amazonensis*, *L. pifanoi*, and *L. venezuelensis*.^{72,98} Other species of *Leishmania* involved in 'New World' disease include *L. guyanensis* and *L. panamensis*,⁹⁹ as well as *L. braziliensis* (once considered an exclusive cause of mucocutaneous disease). A series of cases caused by this species found mucosal disease in only 12.7% of cases.¹⁰⁰ No cases of mucosal disease were recorded in a series of 71 cases of leishmaniasis from Brazil; in cases tested, all were due to *L. braziliensis*.¹⁰¹ *Leishmania infantum*, long considered an exclusive cause of visceral leishmaniasis (see later), has now been identified in cutaneous leishmaniasis.^{102–104} These two examples highlight the artificiality of 'matching' organisms to each of the three categories (cutaneous, mucocutaneous, and visceral) in the traditional classification.

Acute, chronic, recidivous, disseminated, tardive, and leishmanid forms are recognized.^{51,94} The *acute* lesions are usually single papules, which become nodules, ulcerate, and heal, leaving a scar.^{84,105–107} Panniculitis resembling nodular vasculitis has been described,^{108,109} and it has even been reported in association with visceral leishmaniasis.¹¹⁰ Lesions are usually present on exposed areas of the skin such as the face, arms, and lower legs.^{111,112} The ear is sometimes involved, but this site is more commonly affected in forest workers in Mexico and Central America with 'New World' disease.¹¹³ The lip and genital region are other sites that can be involved.^{104,114,115} Unusual presentations include paronychia, chancriform, pseudolymphomatous, annular, palmoplantar, zosteriform, and erysipeloid forms.^{116–122}

Chronic lesions, which persist for 1 or 2 years, are single, or occasionally multiple, raised non-ulcerated plaques. They are notorious for mimicking a wide variety of other conditions. Examples include sarcoidosis, rosacea, or papulonecrotic tuberculid (papulonodular lesions); appendageal tumors or amelanotic melanoma (tumoral lesions); and verrucae, deep fungal infections, or tuberculosis verrucosa cutis (verruiform papulonodular lesions).¹²³

The *recidivous* (lupoid) form consists of erythematous papules, often circinate, near the scars of previously healed lesions.^{74,124–131} The recidivous form is mostly seen with so-called 'Old World' leishmaniasis caused by *L. tropica*.¹³² Several cases have now been reported from South America ('New World').^{133,134}

The *disseminated* form (primary diffuse cutaneous leishmaniasis) develops in anergic individuals as widespread nodules and macules, without ulceration or visceral involvement.^{135–137} It is seen, not uncommonly, in patients with HIV infection.^{138–140} Localized lesions may still be seen in patients who are immunosuppressed; lesions are not always

disseminated.¹⁴¹ Reactivation of dormant infection may also occur.¹⁴² The disseminated form is quite rare in *L. tropica* infections, but less so with *L. mexicana*.^{98,143} Sporotrichoid,^{119,144,145} psoriasiform,¹⁴⁶ mass,¹⁴⁷ and satellite lesions^{148,149} are very uncommon clinical manifestations of cutaneous leishmaniasis.

A *tardive* form, in which a lesion developed at the site of recent cutaneous surgery, has been reported.¹⁵⁰ The likely source of infection was encountered more than 50 years previously.¹⁵⁰ *Leishmanid* is a very rare form in which eruptions appear in a different site from the primary focus of cutaneous leishmaniasis.⁵¹

A myriad of treatment regimens have been used. A recent report highlighted the fact that the quality of the treatment studies has generally been poor.¹⁵¹ Antimonials have long been the backbone of treatment schedules,^{94,130,152,153} with a recent systematic review recording a cure rate of 76.5% with these drugs.¹⁵⁴ Other reports have demonstrated variable outcomes with fluconazole,⁵⁶ itraconazole,^{155,156} miltefosine,^{157,158} pentoxifylline,¹⁵⁹ liposomal amphotericin B,^{160–162} and vaccines.¹⁶³ Therapies such as current field-radio frequency,^{56,57,164} cryo-surgery,^{165,166} and photodynamic therapy have been used successfully.^{167–169} Cutaneous lesions in patients with HIV infection¹⁷⁰ and the disseminated form are much more difficult to treat.¹⁷¹ Treatment of a patient with localized disease with IFN- γ induced a granulomatous reaction in the lesion.¹⁷² An assessment of the effectiveness of treatment can be made by monitoring the parasite load in skin biopsies using quantitative nucleic acid sequence-based amplification.¹⁷³

Histopathology

In *acute* lesions, there is a massive dermal infiltrate of lymphocytes, parasitized macrophages, epithelioid cells and occasional giant cells, plasma cells, and sometimes a few eosinophils (Fig. 27.4).^{174,175} Both CD4⁺ and CD8⁺ lymphocytes are present.⁹⁹ Variable numbers of neutrophils are present in the upper dermis. A Turkish study of 54 patients (24 of whom were from Syria) noted hyperkeratosis, follicular plugging, acanthosis, parakeratosis, or epidermal atrophy as the most frequent epidermal findings and lymphocytic–histiocytic inflammation, granuloma formation, and plasmacellular infiltration as the most common dermal changes; amastigotes were identified in two-thirds of the cases.¹⁷⁶ Granulated calcific Michaelis–Gutmann bodies have been reported in the cytoplasm of macrophages in two cases.¹⁷⁷ Rarely, the inflammatory infiltrate extends around small nerves in the deep dermis in a manner similar to leprosy.¹⁷⁸ Panniculitic lesions feature dense, diffuse infiltrates involving both septa and lobules, containing lymphocytes, plasma cells, neutrophils, and granulomatous elements, with foci of fat necrosis and fragmented organisms.^{108,109} The parasites are round to oval basophilic structures, 2–4 μ m in size. They have an eccentrically located kinetoplast. Their lack of a capsule is helpful in distinguishing them from *Histoplasma capsulatum*. Although organisms can be seen in macrophages in hematoxylin and eosin (H&E)-stained sections (Fig. 27.5), the morphological details are better seen on a Giemsa stain, preferably of a slit-skin smear,¹⁷⁹ when available, structural details of *Leishmania* amastigotes can be observed with electron microscopy (Fig. 27.6). Organisms tend to localize at the periphery of the macrophages, the so-called ‘marquee’ sign (Fig. 27.7). The epidermis shows hyperkeratosis and acanthosis, but sometimes atrophy, ulceration, or intraepidermal abscesses (Fig. 27.8).^{144,180} Pseudoepitheliomatous hyperplasia is present in some long-standing lesions.

With increasing *chronicity*, there is a reduction in the number of parasitized macrophages and the appearance of small tuberculoid granulomas that consist predominantly of epithelioid cells and histiocytes with occasional giant cells.¹⁸⁰ Central necrosis is rare.¹⁸¹ There is an intervening mild to moderate mononuclear cell infiltrate. Langerhans cells in the epidermis also decrease with chronicity of the lesions.¹⁸²

Cutaneous leishmaniasis is frequently misdiagnosed in countries where it is not endemic, particularly if organisms are not seen.¹⁸³ It

Figure 27.4 Leishmaniasis. The dermal infiltrate is composed of lymphocytes, some plasma cells, and parasitized macrophages. (H&E)

may be misinterpreted as sarcoidosis, foreign body reaction, granulomatous rosacea, and even granuloma annulare.¹⁸³

In the *recidivous* form, the appearances resemble those seen in lupus vulgaris, with tubercles surrounded by lymphocytes and histiocytes with some giant cells.^{74,180} However, there is no necrosis and only sparse plasma cells (Fig. 27.9). Occasional organisms may be found on careful search. PCR can be used to demonstrate the presence of DNA of *Leishmania* amastigotes in tissue sections⁷⁴ or lesional scrapings.⁵⁶ It is the most sensitive method for diagnosis.^{56,82,184,185} An immunohistochemical method using a monoclonal anti-*Leishmania* (G2D10) antibody has been developed.¹⁸⁶ It has only marginally greater sensitivity and specificity than the routine H&E stain.

In the *disseminated* anergic lesions, the infiltrate is almost entirely composed of parasitized macrophages, with scant lymphocytes.¹⁸⁷ Eosinophils were abundant in one reported case.¹⁸⁸

Mucocutaneous leishmaniasis

The initial lesions of mucocutaneous (American) leishmaniasis, caused by *Leishmania (Viannia) braziliensis*, resemble those seen in the cutaneous form.¹⁸⁹ In an increasing number of cases, only cutaneous

Figure 27.5 Leishmaniasis. Numerous organisms are present in the cytoplasm of macrophages. (H&E)

lesions are being seen with this organism (discussed previously).^{190–192} Vegetating, verrucous, and sporotrichoid¹⁹³ lesions may also occur. In up to 20% of cases, destructive ulcerative lesions of mucous membranes develop, particularly in the tongue, nasopharynx, and at body orifices.^{194,195} This complication, known as espondia, may develop up to 25 years after the apparent clinical cure of the primary lesion.^{53,189} Hypopigmented patches resembling lesions of borderline tuberculoid leprosy have also been described.¹⁹⁶ A five-stage clinical grading system for mucocutaneous leishmaniasis has been proposed that is based largely on degrees of progression and tissue destruction associated with the disease.¹⁹⁷ Mucosal leishmaniasis caused by *L. infantum* has been reported.¹⁹⁸ Mucocutaneous leishmaniasis is found in Central and South America or in travelers from those areas.^{199,200} The disseminated anergic form is a rare complication;¹⁸⁷ it may occur in patients with AIDS²⁰¹ or in immunosuppressed individuals.²⁰²

Histopathology

The appearances resemble those seen in the acute cutaneous form, although the number of organisms is considerably smaller and occasional tuberculoid granulomas may be seen. Suppurative granulomas have been described.¹⁸⁹ The mucosal lesions show nonspecific chronic

Figure 27.6 Leishmaniasis. Ultrastructure of a lesion from a partly treated patient. This amastigote shows a nucleus (12:00 o'clock) and a cross-section of the flagellum (3:00 o'clock). A portion of the rod-shaped kinetoplast can be seen just to the left of the flagellum.

Figure 27.7 Leishmaniasis. Some of the organisms can be seen to line up along the periphery of macrophages – the 'marquee sign'. At this magnification, kinetoplasts can barely be discerned in some of the organisms (arrows). (H&E, oil immersion, ×1000)

inflammation, with only a few parasitized macrophages. Pseudoepitheliomatous hyperplasia may be prominent in some lesions, particularly at the periphery.¹⁹⁹ There may be fibrosis in the dermis in cicatricial lesions.¹⁹⁹ A favorable prognostic feature is the presence of necrosis with a reactive response.²⁰³

Visceral leishmaniasis

Visceral leishmaniasis (kala-azar), caused by *L. donovani*, results in fever, anemia, and hepatosplenomegaly.¹⁸⁷ It is endemic in many tropical countries. Cutaneous involvement (post-kala-azar dermal leishmaniasis) develops in approximately 5% of cases (10–20% of Indian cases), approximately 1–3 years or more after the original infection.^{204–206} This figure was much higher in a recent series.²⁰⁷ This cutaneous form

Figure 27.8 Leishmaniasis. (A) An ulcerated lesion in a soldier recently returned from Iraq. (B) Parasitized macrophages are present. (H&E)

is most frequent in countries of the Indian subcontinent.^{208–210} High levels of IL-10 in the peripheral blood of patients with visceral leishmaniasis are predictive of the development of post-kala-azar dermal leishmaniasis.²¹¹ The lesions comprise areas of erythema (usually on the face), macules that may be hyper- or hypopigmented (usually on the trunk),²¹² and nodules (usually on the face but not infrequently on the limbs).^{204,213,214} The tongue is rarely involved.^{66,215} A lupoid plaque is a rare manifestation.²¹⁶ Lesions may clinically resemble leprosy, but they differ by having normal sensation.²⁰⁷ Coexistence with borderline tuberculoid leprosy has been reported.^{217,218} Cutaneous lesions have been reported during the course of visceral leishmaniasis in patients with AIDS;^{161,219–225} they may develop following highly active antiretroviral therapy (HAART)-induced immune recovery.²²⁶ Rare variants of AIDS-associated cases have included the occurrence of leishmaniasis in lesions of herpes zoster,²²⁷ parasitization of cells in a dermatofibroma,²²⁸ and the development of dermatomyositis-like lesions.²²⁹

Subspecies within the *L. donovani* complex include *L. donovani*, *L. infantum*, *L. chagasi*, and *L. nilotica*.⁷² An *L. donovani* promastigote

Figure 27.9 Leishmania recidivans. Granulomatous inflammation predominates. Only rare organisms were present in this specimen. (H&E)

membrane antigen (LAg)-based enzyme-linked immunosorbent assay and dipstick system may prove to be an easy and low-cost method of diagnosing post-kala-azar dermal leishmaniasis.²³⁰

Ketoconazole and allopurinol produce side effects or have a slow response when used in the treatment of post-kala-azar dermal leishmaniasis.²³¹ Oral miltefosine has shown promise.²³¹

Histopathology

There is usually a dense infiltrate of inflammatory cells in the upper dermis beneath an atrophic epidermis.²¹⁰ Acanthosis is sometimes present.²³² The infiltrate is composed of a variable admixture of macrophages, lymphocytes, plasma cells, and epithelioid cells.²³³ Occasional eosinophils can usually be found. Neutrophils are present in a few cases.²¹³ There may be an occasional tuberculoid granuloma. In nodular lesions, the infiltrate may occupy the entire thickness of the dermis.²¹³ In patients with a neuropathy, the inflammatory cell infiltrate shows perineural accentuation.²³⁴ Follicular plugging is often present, particularly in lesions from the face.²⁰⁹ There are microscopic differences between reported cases from Sudan and those from India. In Sudanese patients, epidermal changes are variable but with acute basilar keratinocyte degeneration; dermal infiltrates are lymphohistiocytic (with mostly CD3⁺ T cells and with CD4⁺ cells predominating over CD8⁺ cells) and only sparse plasma cells. Neuritis involving small cutaneous nerves is seen.²³⁵ In contrast, Indian patients have epidermal atrophy, prominent follicular plugging, and only rare nerve involvement.²³⁵ Organisms (Leishman–Donovan bodies) are nearly always present, but their number varies from case to case and from lesion to lesion. They may be visualized better in sections stained with Weigert iron hematoxylin than in those stained with H&E or the Giemsa stain.²¹³ An immunohistochemical method using G2D10 antibody is a more sensitive method of detecting Leishman–Donovan bodies than H&E section.²³⁶ Immunohistochemistry shows a preponderance of CD3⁺ T cells. There are few B cells.²³² There are conflicting reports on whether CD4⁺ cells or CD8⁺ cells predominate.^{232,237}

Fine needle aspiration cytology is an effective diagnostic technique for demonstrating *L. donovani* amastigotes in cutaneous lesions.²¹¹ Slit aspirates are also useful for this purpose.²³⁸

Differential diagnosis

Leishmaniasis must be distinguished from other disorders characterized by parasitized histiocytes, including histoplasmosis, granuloma inguinale, rhinoscleroma, and toxoplasmosis. Detailed methods of

differentiating these and other infectious diseases are presented in the discussion of histoplasmosis in Chapter 25. Chronic forms of leishmaniasis with granulomatous infiltrates can resemble sarcoidosis or forms of tuberculosis (particularly lupus vulgaris) and may require careful search for organisms, differential staining, or culture studies to reach the correct diagnosis. In a clinicopathologic study of 125 cases of histopathologically or PCR-confirmed 'Old World' cutaneous leishmaniasis (due to *L. tropica*), 57 of these cases were identified as having atypical histopathological features mimicking other conditions. These included squamous cell carcinoma (20 cases); deep fungal infection (with pseudoepitheliomatous hyperplasia and intraepidermal neutrophilic abscesses; 7 cases); secondary syphilis (with psoriasiform hyperplasia and vacuolar alteration of the basilar layer; 5 cases); panniculitis (5 cases); tuberculosis (4 cases); mycosis fungoides (3 cases); sarcoidosis or pityriasis lichenoides acuta (2 cases each); and indeterminate leprosy, spongiotic dermatitis, lichen planus, or anaplastic large T-cell lymphoma (1 case each).²³⁹ Organisms seen in fine needle aspirates of post-kala-azar dermal leishmaniasis lesions should be distinguished from *Histoplasma*, *Candida glabrata*, or *Cryptococcus neoformans*; an absence of budding (e.g., *Histoplasma*) and performance of fungal stains should help in excluding these other conditions.²¹¹

TRICHOMONIASIS

Although genital infections with *Trichomonas vaginalis* are common, cutaneous infections with this organism are exceedingly rare and usually confined to the median raphe of the penis.²⁴⁰ An underlying cyst or tract is usually present. Trichomonads may be demonstrated by microscopy of the pus, drained from the abscess that forms.

GIARDIASIS

The cutaneous manifestations most commonly associated with gastrointestinal infection by *Giardia lamblia* are urticaria and angioedema. Other associations have included atopic dermatitis and a papulovesicular eruption that cleared on treatment of the parasite.²⁴¹ The protozoan has not been found in skin lesions.

COCCIDIA

Coccidia have both asexual and sexual cycles. They are usually acquired from contaminated food or water. They are particularly important in immunocompromised patients. They include the genera *Cryptosporidium*, *Sarcocystis*, and *Toxoplasma*. Members of the cat family are the only known definite hosts for the sexual stages of *Toxoplasma gondii*. They are an important reservoir of infection. Congenital infection is the other important route of transmission.

TOXOPLASMOSIS

There are two clinical forms of toxoplasmosis, congenital and acquired.^{242,243} The acquired form is seen most often in immunocompromised patients.²⁴⁴ Skin changes in both are rare and not clinically distinctive.²⁴⁵ Macular, hemorrhagic, and even exfoliative lesions have been reported in congenital toxoplasmosis,²⁴⁶ whereas in the acquired form the lesions have been described as maculopapular, hemorrhagic, lichenoid,²⁴⁷ nodular, and erythema multiforme-like.^{246,248} Varicella-like vesicular lesions have been described.²⁴⁹ There have been several reports of a dermatomyositis-like syndrome.^{250,251} The report of acute toxoplasmosis presenting as erythroderma²⁵² has subsequently been challenged.²⁵³

Histopathology

Pseudoepitheliomatous hyperplasia may develop in a few cases.²⁴⁸ There is a superficial and mid-dermal perivascular lymphohistiocytic infiltrate. The histology has resembled dermatomyositis in cases presenting with a dermatomyositis-like syndrome. In approximately half the cases, parasites (trophozoites) can be seen within the cytoplasm of macrophages, in the form of pseudocysts, lying free in the dermis,²⁴⁸ or rarely within the epidermis,²⁴⁴ eccrine sweat ducts (Fig. 27.10), or arrector pili muscle. They can be seen with H&E stain as small basophilic bodies measuring from 2 to 6 μ m in diameter. They also stain with PAS (a feature of bradyzoites – the slowly replicating form of the organism) and Giemsa methods; they are negative with GMS or Grocott silver stains. Immunohistochemical staining for toxoplasma antigen can also be used (Fig. 27.11),²⁵⁴ and PCR methodology has also been employed in selected cases.²⁵⁵ Some of the rare histological expressions of the disease have been reviewed.²⁵⁶

Differential diagnosis

Although toxoplasmosis lesions may show 'parasitized histiocytes' on biopsy, they differ from other diseases with that feature in that

Figure 27.10 Toxoplasmosis. Two cysts containing the organisms are present in an eccrine sweat duct that displays syringometaplasia due to chemotherapy effect. (H&E)

Figure 27.11 Toxoplasmosis. The organisms show positive staining for toxoplasma antigen. (Immunoperoxidase; stain courtesy of Dr JP Dubey, U.S. Department of Agriculture, Beltsville, MD)

organisms may also be found, singly or in pseudocysts, particularly within epithelial structures. The tachyzoites are positive for PAS, but they do not display the crisp, curved cell wall staining expected with *Histoplasma* organisms, and budding forms are not observed. Negative staining with GMS or Grocott methods may help distinguish toxoplasmosis from other 'parasitized histiocyte' disorders whose organisms are positive for silver stains, including histoplasmosis and rhinoscleroma. Although *Leishmania* also typically do not stain with silver stains, the presence of a kinetoplast and the characteristic arrangement of these organisms within macrophages (the 'marquee sign') are not features of *Toxoplasma*.

SPOROZOA

The sporozoa include *Plasmodium* spp. and *Babesia* spp., the organisms that cause malaria and babesiosis, respectively. Only babesiosis is considered further.

BABESIOSIS

Babesiosis is a rare protozoal zoonosis caused by a hemoproteozoan of the genus *Babesia*.²⁵⁷ It is transmitted by the bites of ticks of the genus *Ixodes*.²⁵⁷ Few cases of human babesiosis have been reported, but most cases of the disease go unreported or undetected.²⁵⁸ It is seen particularly in patients who are immunosuppressed or have undergone splenectomy. It may be transmitted by blood transfusions.²⁵⁸

In the United States, most cases have been in the Northeast and Midwest. *Babesia microti* is usually involved. In Europe, *B. divergens* has caused most cases, particularly in asplenic patients. Onset of the disease is insidious, often with mild flu-like symptoms. Cutaneous lesions are rare. An annular erythema with some resemblance to necrolytic migratory erythema has been reported.²⁵⁷

Histopathology

The patient with the annular erythema referred to previously had histopathological features said to be compatible with necrolytic migratory erythema. There was subcorneal pustulation with adjacent parakeratosis, but the vacuolated keratinocytes reported were difficult to see in the published photomicrograph.²⁵⁷ Dermal inflammatory changes were superficial and mild.

MISCELLANEOUS

Although traditionally classified as a protozoan, *Pneumocystis jiroveci* (formerly *P. carinii*) has recently been reclassified as a fungus on the basis of several morphological features. Pneumocystosis is considered here by tradition.

PNEUMOCYSTOSIS

Pneumocystosis refers to an opportunistic infection caused by *Pneumocystis jiroveci*. Culture of *Pneumocystis* is difficult, although short-term *in vitro* methods have been developed.²⁵⁹ This organism causes pneumonia in immunocompromised individuals. Typical symptoms include fever, nonproductive cough, and dyspnea on exertion. Extrapulmonary involvement does occur; cutaneous pneumocystosis is a rare

Figure 27.12 Pneumocystosis. The characteristic cysts of *Pneumocystis* can be identified with GMS stain. Some of these have a 'collapsed' appearance. (GMS)

infection seen particularly in patients with AIDS.^{260,261} There may be polypoid lesions in the external auditory canals²⁶¹ or lesions in other locations manifesting as papules with a resemblance to molluscum contagiosum,²⁶² hyperpigmented nodules,²⁶³ or bluish macules that mimic Kaposi's sarcoma.^{262,264} Several reports describe mixed infections with *Pneumocystis* and *Cryptococcus*.^{261,265} Treatment includes trimethoprim-sulfamethoxazole.

Histopathology

Biopsies often show minimal inflammation.²⁶⁶ Sections show perivascular mantles of amphophilic or eosinophilic, foamy to finely stippled material similar to that seen in pulmonary pneumocystosis.²⁶⁰ Within the foamy material are basophilic dots that represent nuclei of the organism. Small cysts can also be identified, especially with GMS stain but also with other methods, such as toluidine blue; these often have a collapsed appearance that take on a crescent configuration (Fig. 27.12). Focal argyrophilic thickenings of the internal cyst walls can also be identified and can be of diagnostic importance.²⁶⁷ Confirmation of the diagnosis can be achieved with direct immunofluorescence study²⁶⁸ and PCR technology.²⁶⁹

Differential diagnosis

Pneumocystis infection, although rare, often has a distinctive microscopic appearance. Diagnostic problems can arise in distinguishing the organisms from other yeast-like fungi, particularly *Cryptococcus*, *Histoplasma*, and *Candida*, and combinations of these infections can also occur, even within the same lesion. However, *Pneumocystis* organisms do not reproduce by budding, and the collapsed appearance of the cysts and argyrophilic foci within cyst walls are characteristic.

Marine injuries

Introduction	758	Echinoderms	759	Seaweed	759
Cnidarians	758	Sponges	759	Venomous fish	759
Molluscs	759				

INTRODUCTION

Cutaneous injuries from various forms of marine life are uncommon recreational and occupational hazards. Many of the species encountered have a specific geographic localization. In most instances, a localized urticarial and inflammatory lesion results at the point of injury, but this may be accompanied by a laceration if a sharp dorsal spine is involved. The death of the noted marine adventurer Steve Irwin (the 'Crocodile Hunter') as the consequence of a penetrating injury to his heart from a stingray barb was a reminder of the dangers some marine creatures pose. Severe systemic reactions and even fatality may result from the toxins of some marine organisms.

There have been several reviews of the cutaneous manifestations of marine animal injuries,¹⁻⁴ including Fisher's *Atlas of Aquatic Dermatology*.⁵ Although of great dermatological and medical interest, these cutaneous lesions are of little dermatopathological importance. Biopsies are rarely taken, and if they are, the findings, with several exceptions, are not diagnostically or etiologically specific.

In the brief account that follows, various categories of marine organisms are considered.

CNIDARIANS

Although the phylum Cnidaria, formerly Coelenterata, has more than 9000 species, fewer than 80 are of clinical significance.²⁻⁵ The toxic effects of cnidarians (coelenterates) result from contact with the nematocyst, a coiled thread-like tube, found particularly on the tentacles, which pierces the skin on contact. This results in the formation of linear erythematous plaques;⁶ the toxin contained in the nematocysts of some species is capable of producing such diverse reactions as erythema, urticaria, a burning sensation, or, rarely, fatal anaphylaxis and cardiorespiratory arrest.⁷ The cnidarians of dermatological or medical importance include the Portuguese man-of-war⁸ (*Physalia physalis*) in the class Hydrozoa, the box jellyfish⁹ (*Chironex fleckeri*) in the order Scyphozoa, and the corals in the order Anthozoa. *Physalia physalis* envenomization has also produced linear purpuric papules.¹⁰ Treatment of the stings from *P. physalis* includes deactivation of nematocysts (through saline washing, immersion in 5% acetic acid or 70% isopropyl alcohol, and removal of nematocysts), pain control, and support of vital organs.¹¹

More than 70 deaths have resulted from the sting of the box jellyfish;⁹ an antivenom has been developed against *Chironex fleckeri*.¹² In the areas of contact with the tentacles, linear erythematous and urticarial lesions are produced. These may persist for several days or longer and be followed by postinflammatory pigmentation or keloid formation.¹³ The jellyfish *Stephanoscyphus racemosus* Komai, also known as 'Iramo', and found in Japanese waters, can produce hemorrhagic bullae after contact with its nematocysts.¹⁴

Attention has also been given to the development of delayed and recurrent eruptions, not necessarily at the previous site of contact, which may follow solitary episodes of envenomation by different species of cnidarians.^{13,15-18} An immunological mechanism has been postulated for these delayed or recurrent reactions.^{17,19,20}

In the case of corals, the nematocysts are relatively innocuous, but some coral cuts are slow to heal and are prone to secondary infection and localized persistent inflammatory reactions at the site of contact with coral.^{21,22}

Seabather's eruption is a highly pruritic maculopapular eruption, under swimwear, that occurs after bathing in the ocean.²³ It appears to result from the nematocyst of a cnidarian larva;²³ *Edwardsiella lineata* and *Linuche unguiculata* have been implicated.²⁴⁻²⁶ Ghost anemone dermatitis, produced by *Haloclava producta*, which is also a member of the class Anthozoa, produces a similar dermatosis to

seabather's eruption, although vesiculation often occurs as well. It is found along the east coast of the United States and Gulf of Mexico.²⁷ They should be distinguished from 'swimmer's itch', which occurs primarily in fresh water and is caused by schistosomal cercariae (see p. 762).²⁸ Paresthesias and pruritus, particularly in the axillae, groins, and genital region, can result from contact with *Liriope tetraphylla* medusa, from the class Hydrozoa. It forms a bloom in the shallow waters of the South American Atlantic coast.²⁹

Histopathology

A biopsy from the site of contact with the tentacles of jellyfish (Fig. 28.1) will show nematocyst capsules in the swollen stratum corneum.³⁰ There is some thinning of the malpighian layer, with focal pyknosis of nuclei. With reduced light, fine refractile threads, sometimes continuous with the nematocysts, can be seen penetrating for variable distances into the dermis (Fig. 28.2).³⁰⁻³² The threads are further highlighted with a reticulin stain.

In some of the recurrent eruptions produced by cnidarians, a heavy dermal lymphocytic infiltrate may be present.^{16,17,33} Spongiosis of the overlying epidermis is sometimes present.³⁴ Rare reactions include granulomas, papular urticaria, local necrosis,³⁵ and subcutaneous atrophy.¹⁵ Atypical CD30⁺ lymphocytes have also been reported in a delayed reaction to a Red Sea coral injury.³⁶ Rarely, corals can produce an inflammatory reaction that on biopsy shows the pattern of a persistent arthropod reaction or papular urticaria.²¹

In seabather's eruption, there is a superficial and deep perivascular and interstitial infiltrate of lymphocytes, neutrophils, and eosinophils. Additional changes can include acanthosis, spongiosis, and apoptotic keratinocytes.³⁷

Figure 28.1 A box jellyfish tentacle in cross-section. (H&E)

Figure 28.2 The site of a box jellyfish sting. Nematocysts are present above the stratum corneum. Several fine thread-like tubules penetrate the epidermis. (H&E) (Photograph kindly provided by Dr G Strutton)

MOLLUSCS

The phylum Mollusca includes such well-known delicacies as scallops and oysters, as well as slugs, squid, cone shells, and several types of octopus.⁵ Cone shell snails of the genus *Conus* produce a painful puncture wound if handled carelessly, followed by systemic toxic symptoms that are sometimes fatal.

Another highly venomous mollusc is the blue-ringed octopus (*Hapalochlaena maculosa*). When disturbed, this octopus flashes multiple iridescent blue rings as a warning display.³⁸ Its bite can produce neuromuscular paralysis leading to respiratory failure.³⁹ The puncture wounds on the skin will have surrounding erythema and edema.⁵ An urticarial reaction has also been recorded.⁴⁰

ECHINODERMS

There are approximately 80 venomous species among the 6000 that comprise the phylum Echinodermata.⁵ This phylum includes sea urchins, starfish, and sea cucumbers, all of which possess an array of sharp or toxic spines.

Sea urchins are widely distributed in several tropical and subtropical oceans. Their brittle spines break off in the skin, where they may produce several different lesions. A neurotoxin is present in the spines of some species. There is an immediate reaction with burning pain, followed by edema and erythema. Small nodules may develop several months after the injury. The resulting dermal reaction has been reported as sarcoidal granulomas,⁴¹ although the illustrations suggest noncaseating tuberculoid granulomas.^{41,42} One study found granulomas of sarcoidal, tuberculoid, suppurative, necrobiotic, and foreign body types in 39 biopsies with granulomas.⁴³ A foreign body granulomatous reaction, probably to the debris of a spine, has been observed.⁴⁴ Implantation cysts may also form.⁴¹ Sea urchin spines have been removed by erbium:YAG laser ablation.⁴⁵ Another recommended method is removal by punch biopsy, which has the advantage of avoiding crushing of fragile spines.⁴⁶

A contact dermatitis can result from contact with certain starfish and sea cucumbers.⁴

SPONGES

Several species of sponge can produce a contact dermatitis, and the spicules from some may produce a foreign body reaction if implanted in the skin.⁵ A severe vesicular dermatitis can occur in some people who come in contact with the 'fire sponge', *Tedania ignis*.⁴⁷ It has been suggested that the reaction may be a primary irritant one and not a contact allergic reaction.⁴⁷ An erythema multiforme-like reaction has also been reported that developed 10 days after the contact.⁴⁷

SEAWEED

The blue-green marine alga *Lyngbya majuscula* can produce an acute irritant dermatitis characterized by intraepidermal vesiculation occurring in the bathing suit area.⁴⁸ Histopathologic features include spongiosis with intraepidermal vesiculation, keratinocyte pallor, exocytosis of lymphocytes, and a superficial perivascular infiltrate with occasional neutrophils and eosinophils.⁴⁹ An allergic contact dermatitis can be produced by a completely different species, *Alcyonidium diaphanum*, a member of the phylum Bryozoa, which produces a seaweed-like animal colony known as the sea chervil or Dogger Bank moss.^{5,50} These sea 'mosses' are found on the Dogger Bank and give rise to a pruritic vesiculobullous dermatitis ('Dogger Bank itch') in fishermen who come into contact with them.⁵ It is an allergic contact dermatitis to a sulfoxonium ion, a metabolite produced by the organism.⁵¹

VENOMOUS FISH

Contact with the venomous spines of several marine vertebrates can produce severe systemic reactions that may be fatal. Excruciating pain is usual at the site of the injury. This group includes the stingray, stonefish, weever fish, and catfish.⁵² The stonefish possesses a potent neurotoxin and is the most dangerous in this group.⁵³ The weever fish (*Trachinus draco*) causes erythema, swelling, and pain; its venom contains proteins that produce cell membrane depolarization and hemolysis.⁵⁴ Both the stonefish and the stingray can produce local tissue necrosis, sometimes extensive, in the region of the injury.⁵⁵⁻⁵⁸ A bullous eruption on the dorsal aspect of the hand has followed stingray injury in a domestic aquarium.⁵⁹ TIA⁺ lymphocytes are found in the infiltrate adjacent to the zone of necrosis; these cells may contribute to the delayed healing that is frequently encountered.⁶⁰

Scales from certain species may produce an irritant dermatitis in workers cleaning fish.⁶¹ The lesions are 0.5–1 cm in diameter, raised, and nonscaling.

An erythematous eruption, including facial flushing, accompanied by systemic symptoms may follow the eating of spoiled fish of the families Scomberesocidae and Scombridae (tuna, mackerel, skipjack, and bonito). Bacterial proliferation allows the conversion of histidine in the fish into histamine, which is thought to be responsible for the symptoms.⁶² Measurement of serum tryptase levels may provide a means of distinguishing allergic reactions to various allergens (tryptase levels elevated) from scombroid fish poisoning (tryptase levels normal – due to the different origin of histamine in this syndrome).⁶³ Other toxins that may be involved in scombroid fish poisoning include cadaverine and urocanic acid.⁶⁴ A review of the subject has recently been published.⁶⁵

Cestode infestations	762	Onchocerciasis	764		

INTRODUCTION

Helminthic parasites are responsible for a number of important diseases of tropical countries, including schistosomiasis, caused by the trematode flukes; cysticercosis and sparganosis, resulting from the larvae of certain tapeworms (cestodes); and onchocerciasis, dirofilariasis, and larva migrans occurring as a consequence of nematode infestations.¹ The most common helminth infection in the United States and western Europe – enterobiasis (pinworm) – produces no primary cutaneous pathology, although changes in the perianal region, secondary to scratching, may occur.²

TREMATODE INFESTATIONS

SCHISTOSOMIASIS

It has been estimated that 200 million people are infested with one or other of the three major species of schistosome fluke.³ *Schistosoma haematobium* (found in most of Africa and in the Near East) has a predilection for the bladder, *S. japonicum* (common in areas of the Far East) for the gut, and *S. mansoni* (found in Africa and areas of the Caribbean region and the northeast area of South America) for the portal circulation.^{4,5} Four types of skin lesions have been described:^{6–15}

1. A pruritic, erythematous and urticarial papular rash (cercarial dermatitis, ‘swimmer’s itch’) associated with the penetration of the cercariae through the skin en route to the various venous plexuses to mature¹⁶
2. Urticarial lesions associated with the dissemination of the cercariae or the laying of eggs by the adult flukes
3. Papular, granulomatous, and even warty vegetating lesions of the genital and perineal skin secondary to the deposition of ova in dermal vessels^{13,17,18}
4. Extragenital cutaneous lesions secondary to lodgment of ova and, rarely, worms.^{14,19,20}

Urticarial lesions are more common with *S. japonicum*,⁸ and perineal lesions with *S. haematobium*,^{9,21} whereas extragenital cutaneous manifestations are usually a complication of *S. japonicum* and *S. haematobium* but are quite rare with *S. mansoni*.²² The term ‘bilharziasis’ is used for the ectopic deposition of ova within the dermis.²³ A recently reported case of extragenital cutaneous schistosomiasis clinically resembled Paget’s disease of the breast.²⁴ The late development of squamous cell carcinoma has been reported in the verrucous genital lesions.¹⁰

Cercarial dermatitis may also be seen, rarely, as a result of penetration of the skin by cercariae of species of schistosome that are unable to develop further in humans, being destroyed before they reach the venous plexus.^{10,25} Cercarial dermatitis can also be produced by cercariae of the closely related genus *Trichobilharzia*.²⁶

Enzyme-linked immunosorbent assay (ELISA) methods have been developed to assist in the laboratory diagnosis of schistosomiasis.²⁷

Histopathology

The cercarial dermatitis shows intraepidermal spongiosis with exocytosis of eosinophils and neutrophils, sometimes forming microabscesses.⁸ Cercariae are not usually seen. The dermal reaction is mild, with edema, vascular dilatation, and a mild perivascular inflammatory cell infiltrate and some interstitial eosinophils.

Genital and perineal lesions show hyperkeratosis and acanthosis. There may be prominent pseudoepitheliomatous hyperplasia and, occasionally, focal ulceration or draining sinuses with accompanying

Figure 29.1 An ovum of *Schistosoma* in an area of fibrosis. No reaction is present. (H&E)

acute inflammation.^{7,13} The dermis contains numerous ova, some associated with a granulomatous reaction, including foreign body giant cells. Other eggs are in microabscesses, often containing numerous eosinophils. Flukes may be seen in cutaneous vessels.

Extragenital lesions show numerous ova in the superficial dermis associated with necrobiosis and palisading granulomas.^{11,12,15} Eosinophils, neutrophils, and foreign body giant cells are found in most lesions,²⁸ whereas in later lesions there may be degenerating or calcified ova, plasma cells, and fibroblasts, with variable fibrosis (Fig. 29.1). Identification of ova in late fibrous lesions may be difficult.²²

The ova of the three major species have characteristic features. The ova of *S. haematobium* have an apical spine, those of *S. mansoni* have a lateral spine, and those of *S. japonicum* have no spine.⁸ The ova of *S. mansoni* and *S. japonicum* may be acid fast.

Molecular methods can also be used for diagnosis and species identification, as documented in a recent case in which extraction and amplification of the *Schistosoma* 28S rRNA gene was carried out using material from paraffin-embedded biopsies of skin lesions.²⁹

OTHER TREMATODES

A larval trematode, identified as a mesocercaria of an undescribed species belonging to the subfamily Alariinae, has been removed from an intradermal swelling.³⁰ The lung fluke *Paragonimus westermani* rarely produces a cutaneous inflammatory lesion; it often extends into the subcutis. The lesions may include an abscess containing many eosinophils.^{31,32} An egg of the parasite may be present in the abscess.³³

CESTODE INFESTATIONS

CYSTICERCOSIS

The larval phase of *Taenia solium*, the pork tapeworm, may infect humans as an accidental intermediate host, with the formation of one or more asymptomatic subcutaneous nodules 1–3 cm in diameter.^{34–42} The larvae have a predilection for the chest wall, upper arms, and thighs.⁴³ The nodules are composed of a white cystic structure with an outer membrane containing clear fluid and a cysticercus larva

Figure 29.2 Cysticercosis. Subcutaneous lumps removed from the thighs.

Figure 29.3 Cysticercus larva removed from a subcutaneous 'cyst' of the skin. (H&E)

attached to one edge (Fig. 29.2). Surrounding the gelatinous cyst is a host response of fibrous tissue.

Histopathology

The diagnosis is made by the characteristic appearance of the scolex of the cysticercus larva (Fig. 29.3). The fibrous tissue reaction in the subcutaneous tissue contains a moderate chronic inflammatory cell infiltrate that includes variable numbers of eosinophils (Fig. 29.4). A few scattered giant cells are sometimes present.

SPARGANOSIS

Sparganosis is a rare infestation caused by the larval form of a tape-worm of the genus *Spirometra*.^{44–46} It occurs in many areas of the world, mainly in the tropics. Humans are a second intermediate host. Infestation may result in a subcutaneous nodule that slowly migrates. Bisection of the nodule after excision will reveal a white thread-like worm approximately 1 mm in width and from a few centimeters to 50 cm in length.^{47,48} An example of a lesion mimicking folliculitis has been reported due to infestation by *S. mansoni*.⁴⁹

Figure 29.4 Cysticercosis. The cyst wall is composed of inflamed fibrous tissue and many eosinophils. (H&E)

Figure 29.5 Sparganosis. Portions of worm are present in a subcutaneous cavity. There is an inflammatory reaction in the surrounding tissue and some fibrosis. (H&E) (Photograph kindly supplied by Professor Robin Cooke)

Histopathology

There is a subcutaneous, partly granulomatous, inflammatory mass composed of lymphocytes, plasma cells, neutrophils, and variable numbers of eosinophils.⁵⁰ Portions of worm are usually seen within the mass,⁴⁴ or there may be a cavity where the larva has been (Fig. 29.5). The larva has a flattened structure with both longitudinal and horizontal muscle bundles, giving a 'checkerboard' appearance. A longitudinal excretory canal is also present, and basophilic calcareous corpuscles, a characteristic feature of cestodes, may also be seen scattered in varying numbers throughout the matrix.⁴⁵ Polymerase chain reaction (PCR) and sequencing analysis on tissues from subcutaneous sparganosis have been successful in identifying the responsible species, *Spirometra erinaceieuropaei*, and ruling out the disseminating species, *S. proliferum*. The same investigators developed an immunofluorescence method directed toward the tegument of the parasite.⁵¹

ECHINOCOCCOSIS

Echinococcosis is one of the most widespread parasitic diseases globally, with an estimated 2–3 million cases, one-third of whom are

children. The global burden for human (cystic) echinococcosis due to *Echinococcus multilocularis* has been estimated to be more than that for onchocerciasis, although incidence figures do not seem to reflect this (see later), and similar to that due to African trypanosomiasis (see p. 749).⁵² It is endemic in areas of Asia, including northwest China.⁵²

Cutaneous lesions have been reported on the abdomen in two patients with alveolar echinococcosis, an uncommon parasitic disease of the liver caused by the larvae of *E. multilocularis*.⁵³ A subcutaneous mass composed of multiple cysts diagnosed as echinococcosis developed in the scapular region of a woman without demonstrable visceral disease.⁵⁴ In addition, cutaneous fistulae have been reported in association with alveolar echinococcosis.⁵⁵ This cestode is closely related to *E. granulosus*, which causes hydatid disease of the liver and other sites. Subcutaneous lesions are rare with this latter species.⁵⁶ Anaphylactic shock, with cutaneous urticarial features, has been reported with hepatic hydatid disease.⁵⁷

Histopathology

The lesions were characterized by a dense granulomatous infiltrate within the dermis, surrounding larval elements.⁵³

NEMATODE INFESTATIONS

ONCHOCERCIASIS

Onchocerciasis, which is common in tropical Africa, the Yemen, and Central and South America, is caused by the nematode *Onchocerca volvulus*.^{58–61} It has been estimated that 18 million people worldwide are infested with this nematode,⁶² despite massive intervention campaigns.⁶³ The larvae are transmitted by several species of flies of the genus *Simulium*.⁶⁴ Onchocerciasis mainly affects people living close to fast-flowing rivers, where the flies breed.⁶¹ The larvae mature into adult worms in the subcutaneous tissue, where they form nontender subcutaneous nodules 2.5–10 cm in diameter. The nodules, which may occur anywhere on the body, are either isolated or grouped in large conglomerations. Bilateral swellings in the inguinal region (hanging groin) may develop.⁶⁵ They may contain one or several tightly coiled worms, which may live for many years.

The adult worms produce microfilariae, which are found in the neighboring lymphatics. The microfilariae may migrate to the dermis and eye. Visual impairment and blindness (river blindness) is an important complication of onchocerciasis.⁶⁶ Onchocercal dermatitis, which results from infiltration of the skin by these microfilariae, is a pruritic papular rash with altered pigmentation.^{59,67} The dermatitis is typically generalized, but an eruption localized to one limb, usually a leg, is found in the northern Sudan and also in Yemen, where it is known as sowda.⁶⁸ Pruritic urticarial plaques may also form.⁶⁹ Serodiagnosis can be made by a recombinant hybrid protein-based ELISA method.⁷⁰

It has long been noted that residents of endemic areas show striking differences in infection intensity, which cannot be explained by differences in exposure alone.⁶³ Some remain free of infection. Genetic resistance to infection with this parasite appears to be linked to chromosome 2p.⁶³

Ivermectin, an anthelmintic, is used to treat the disease. Unfortunately, it is not available in some endemic areas because of cost.⁶⁴ Vigorous public health efforts have been successful in limiting onchocerciasis in the Americas, making possible the elimination of this disease from the Western Hemisphere in the near future.⁷¹

Histopathology^{72–74}

The subcutaneous nodules have an outer wall of dense fibrous tissue that usually extends between the worms (Fig. 29.6). Centrally, there is granulation tissue and a mixed inflammatory cell infiltrate in early

Figure 29.6 (A) Onchocerciasis. (B) Several fine coiled microfilariae are present in the fibrous tissue that surrounds the worm. (H&E)

lesions, although in long-standing lesions in which the worms are dead there is only dense fibrous tissue, with some calcification and foreign body giant cells and a chronic inflammatory cell infiltrate.^{65,75} Eosinophils are usually present at all stages. Microfilariae may be seen in lymphatics in this region.

In onchocercal dermatitis, there is a light superficial and deep infiltrate of chronic inflammatory cells and eosinophils in the dermis. Sometimes the infiltrate is heavy.⁷⁶ Microfilariae may be seen in slits between collagen bundles in the upper dermis.^{73,77} Eosinophils and eosinophil major basic protein are usually present around degenerating microfilariae.^{68,72} There is progressive fibrosis of the dermis. The epidermis shows acanthosis and hyperkeratosis. The highest numbers of microfilariae are usually found in the depigmented areas.⁶²

GNATHOSTOMIASIS

Gnathostoma spinigerum is endemic in Southeast Asia and Japan. Other species of *Gnathostoma* are rarely implicated.^{78–80} Until recently, it has been rare in other countries, including the Americas.⁸¹ No cases of cutaneous gnathostomiasis have been reported from India, although intraocular gnathostomiasis has been reported.⁸² Hundreds of cases of gnathostomiasis have been reported from Mexico, where it is becoming a public health problem.⁸³ Human infestation results from eating uncooked, infested meat from the second intermediate host, such as

pigs, chickens, and freshwater fish of the genus *Ophicephalus*.⁸⁴ A case has been reported from the United States in a woman whose only known exposure was the regular consumption of sushi.⁸⁵ In the cases reported from Mexico, the suspected source of infection is the raw fish in the popular dish 'ceviche'.⁸³ The nematode may produce migratory cutaneous swellings with localized erythema (nodular migratory panniculitis), which is common in the cases from Mexico, or a true creeping eruption and pseudofurunculosis, which is seen at the site of exit of the worm through the skin.^{84–89} Excoriation of a pruritic patch may reveal the worm, which measures up to 3 cm in length.

Histopathology⁸⁹

In one large series, in which skin biopsies from 66 patients were reviewed, all biopsies showed a heavy inflammatory infiltrate involving the dermis and subcutis. The infiltrates were composed mostly of eosinophils with some admixed lymphocytes and a few neutrophils. Plasma cells were present in a few cases. Flame figures were rare, and six cases showed an eosinophilic vasculitis. Focal spongiosis was present in some cases, and edema of the papillary dermis was observed in 36 of the 66 biopsies. Larvae were found in 15 cases, and in 12 cases, the worm was retrieved during the biopsy procedure. In a recent case, the larva was found in a necrotic focus in the reticular dermis; it featured lateral cords, a muscular esophagus, and an intestine containing a brush border and multinucleate cells.⁸⁵ Other features of third-stage larvae include cervical sacs at the upper cervical level and reproductive organ at mid-body level; intestinal cells have approximately three nuclei per cell.⁹⁰

DIROFILARIASIS

Human infection with *Dirofilaria* spp. is uncommon except in endemic areas, notably the Mediterranean region.^{91–97} The usual species found in this region is *D. repens*, which may cause subcutaneous nodules.⁹⁸ In the case of *D. immitis* (the dog heartworm), pulmonary lesions, which are usually asymptomatic, can also occur.⁹⁹ Skin lesions are usually solitary, erythematous, and tender subcutaneous nodules.^{100–102} Sometimes there is a sensation of 'movement' under the skin.¹⁰³

Histopathology

The center of the nodule contains a degenerating filaria with a thick laminated cuticle, distinct longitudinal ridges and large lateral cords, as well as typical musculature.^{104,105} There is an intense surrounding inflammatory reaction of lymphocytes, plasma cells, histiocytes, eosinophils, and sometimes giant cells. There is usually central suppuration, and neutrophils may extend out into the adjacent inflammatory zone.¹⁰⁴ The diagnostic histological features of various zoonotic filariae in tissue sections have been reviewed by Gutierrez.⁹³

LARVA MIGRANS

Cutaneous larva migrans commonly occurs in tropical and subtropical countries; most cases seen in the United States and Great Britain have been acquired during travel abroad, but cases contracted in these countries have been reported.^{106–110} It is a self-limiting eruption caused by the intracutaneous wanderings of hookworm and certain other nematode larvae.^{111–114} The creeping eruption caused by fly larvae is usually considered separately. It is known as migratory myiasis and is not due to a nematode.¹¹⁵ In larva migrans, there are pruritic papules that form serpiginous tunnels, which are at first erythematous but soon become elevated and vesicular. There is a predilection for the feet and other exposed sites, although in one study from an urban slum in Brazil in which 3.1% of the inhabitants examined had this infestation, no case involving the feet was found.¹¹⁶ Lesions are usually localized, but widespread disease, acquired from sitting on the sand in tropical beach

resorts, has been reported.¹¹⁷ Bullae may rarely form.^{118–120} Folliculitis, usually on the buttocks, is another manifestation of the disease. It presents as follicular papules and pustules.¹²¹ The linear burrows may be in the same area or in a different area to the folliculitis.^{122,123} The lesion may extend several millimeters per day. Older parts of the track may become crusted. The disease has a limited duration because the larvae are unable to complete their life cycle in the human body and usually die within weeks to months.^{124,125} Löffler's syndrome has uncommonly been reported in association with cutaneous larva migrans.^{126,127}

Epiluminescence microscopy has been used, with mixed success, in the attempted clinical diagnosis of this condition.¹²⁸

Larva migrans is most commonly caused by larvae of *Ancylostoma braziliense*, a hookworm of dogs and cats, but *Necator americanus* may give a creeping eruption of shorter duration.¹ Other hookworms that may produce cutaneous larva migrans include *Ancylostoma caninum*, *Uncinaria stenocephala*, and *Bunostomum phlebotomum*.

A deep subcutaneous form of larva migrans may be seen with *Gnathostoma spinigerum*.^{84,86,129} Infection with *Toxocara* sp. may cause visceral and ocular larva migrans, but not the cutaneous form. Urticaria and prurigo are cutaneous manifestations associated with toxocarasis.¹³⁰

The larvae of *Strongyloides stercoralis*, a soil-transmitted helminth, usually provoke little reaction as they migrate through the skin to reach vessels for their passage to the lung. In some individuals with strongyloidiasis, a variant of larva migrans is found with a rapidly progressing linear urticarial lesion, which may extend at up to 10 cm per hour.^{131,132} The term larva currens (racing larva) has been used for these cases.^{132–135} There is still a high incidence of *Strongyloides stercoralis* infestation in former prisoners of war interned many years ago in Southeast Asia.^{136–138} In one series, almost one-third had suffered episodes of larva currens.¹³⁹ Infestation is now being seen in personnel sent to the Solomon Islands for security duties.¹⁴⁰ Another cutaneous manifestation of strongyloidiasis is the presence of widespread petechiae and purpura.¹⁴¹ These features are seen in immunosuppressed patients with disseminated infections.^{132,142–146} This *Strongyloides* hyperinfection syndrome, as it is known, is an emerging health problem with a high mortality rate.¹⁴⁷ Prurigo nodularis and lichen simplex chronicus are further manifestations of infection with this parasite.^{148–150}

A creeping eruption caused by larvae of the suborder Spirurina has been reported from Japan.^{151,152} The eating of raw squid has been implicated in these patients.

An ELISA method can be used for its serodiagnosis, and molecular techniques have been used to identify larvae from cutaneous lesions as *A. braziliense*.¹⁵³ A single dose of ivermectin usually cures this disease.¹²¹ Albendazole, another anthelmintic, can also be used.¹⁴⁰

Histopathology

In larva migrans, there are small cavities in the epidermis corresponding to the track of the larva, although the parasite itself is uncommonly seen in section (Fig. 29.7). There may be a diffuse spongiotic dermatitis, with intraepidermal vesicles containing some eosinophils.¹⁵⁴ There is usually no inflammatory reaction around the larva (when it can be found), whereas there is a mixed inflammatory reaction behind the migrating larva with a superficial dermal infiltrate of neutrophils, lymphocytes, plasma cells, and usually abundant eosinophils.¹⁵⁴ An eosinophilic folliculitis has been recorded.^{123,155,156} In follicular larva migrans, there are upper dermal edema and a perifollicular infiltrate composed of lymphocytes and eosinophils;¹⁵⁷ granulomas have rarely been described, and fragmented or intact larvae have been found in deep portions of hair follicles in only three cases to date.¹²¹

Reports of larva currens have mentioned a perivascular round-cell infiltrate with interstitial eosinophils – a picture common to many parasitic infestations.¹⁵⁸ Larvae were found in the stratum corneum in a case presenting clinically as both larva migrans and larva currens; the

Figure 29.7 Larva migrans. Cross-sectional profiles of the organism are present within the epidermis, associated with adjacent spongiosis. Mild inflammation is noted in the underlying dermis. (H&E)

Figure 29.8 Sections of the nematode *Wuchereria bancrofti* are present in a cavity in the subcutaneous fat. There are numerous eosinophils in the adjacent fat. (H&E)

organisms were highlighted by periodic acid–Schiff staining.¹⁵⁹ In disseminated strongyloidiasis, there are numerous larvae, 9–15 μm in diameter, in the dermal collagen and rarely in the lumina of small blood vessels.^{132,142}

Diagnosis has been aided by dermoscopy, in which yellow-brown oval structures were found to represent the body of the larva. This was confirmed by near-infrared fluorescence imaging, which showed oval bright spots in the same location and orientation as the dermoscopic structures.¹⁶⁰

OTHER NEMATODES

Various other nematodes are sometimes of dermatopathological interest.¹ *Mansonella streptocerca* is found in West Africa. The adult worm lives in the dermis, and microfilariae may also be seen. It usually presents with hypopigmented macules and itching. The adult worms of *Loa loa*, which is endemic in the rain forests of West and Central Africa, live in the subcutaneous tissue and migrate, producing fugitive (Calabar) swellings and temporary inflammation.¹⁶¹ The elevated outline of the subcutaneous worms may be visible on the skin surface.¹⁶² There is high eosinophilia. Liberation of the microfilariae may produce urticarial lesions.¹⁶³ *Wuchereria bancrofti* (Fig. 29.8) and *Brugia malayi* produce lymphangitis and lymphadenopathy, with the later development of elephantiasis.¹⁶⁴ North American *Brugia* species rarely cause zoonotic infections in humans. Humans acquire the disease through a mosquito bite.¹⁰² The worm matures to an adult without reproducing. There are no circulating microfilariae. No treatment, other than surgical excision of the lesion, is required.¹⁰² A deep cutaneous granulomatous and eosinophilic reaction with fibrosis is found surrounding the parasite.¹⁰² Filarial lymphedema affects an estimated 15 million people worldwide.¹⁶⁵ Its course is complicated by periodic episodes of acute dermatolymphangioadenitis (ADLA), which may also lead to disease progression.¹⁶⁵ Further discussion is beyond the scope of this chapter.

Dracunculus medinensis may produce a blistering lesion due to the migration of the worm, which will eventually be extruded through rupture of the bleb. The female worm measures 70–120 cm in length and is coiled through the subcutaneous tissues. The anterior end is surrounded by granulation tissue containing a mixed inflammatory

infiltrate, and there is fibrosis and some inflammation in the deeper parts.

Trichinella spiralis may produce variable clinical lesions ranging from urticaria to maculopapular lesions following its development in striated muscle.¹⁶⁶ Periorbital edema, hand swelling, and palmar erythema may also occur.¹⁶⁷ The changes are not diagnostic. Trichinosis (trichinellosis) results from ingesting contaminated pork.

There are rare reports of larvae of the soil nematode *Pelodera* (*Rhabditis*) *strongyloides* producing nodular lesions associated with a heavy mixed dermal inflammatory infiltrate and the presence of larvae in tissue sections.^{168,169} Follicular-based pustules may also be present.¹⁷⁰ There are five pathogenic species of *Lagochilascaris*, found in Central and South America. It produces abscesses and fistulas in the skin, particularly in the neck region.¹⁷¹

Larvae of *Diectophyme renale*, the giant kidney worm, which occurs naturally in several fish-eating mammals throughout the world, have been recovered from the subcutaneous tissues of humans on several occasions.¹⁷² In a case presenting as a subcutaneous nodule on the abdomen of a Chinese male living in Japan, biopsy showed sections of a worm in the deep dermis, surrounded by fibrosis and an infiltrate composed of granulomatous elements, eosinophils, lymphocytes, and plasma cells. Among other features, the worm was described as having a polymyarian–coelomyarian muscle layer, eight longitudinal cords, a prominent ventral cord, and a pair of pseudocoelomic membranes at the alimentary tract – features that permitted classification as a dioctophymatid nematode.¹⁷³ Further identification of the organism as *Diectophyme renale* was made possible through PCR amplification and sequencing of small subunit ribosomal DNA and mitochondrial cytochrome subunit *c* oxidase genes.¹⁷³ The fish parasite *Anisakis simplex* is now known to cause cutaneous and/or systemic allergic reactions in humans.^{174,175} Finally, it is not always possible to identify the nematode responsible based on the morphology of the larvae found in tissue sections. Such was the case in a patient with multiple papules and nodules on the face and neck, with a noncreeping eruption.¹⁷⁶

INTRODUCTION

The phylum Arthropoda, which accounts for approximately 75% of animal species, is one of the most important sources of human pathogens.^{1,2} As well as acting as vectors of bacteria, viruses, rickettsiae, chlamydiae, spirochetes, protozoa, and helminths, arthropods may also produce lesions at their portal of entry into the skin. Furthermore, immunological reactions to the parasite or its parts may result in more widely disseminated cutaneous lesions. Specific examples of arthropod-related diseases include mosquito-borne diseases such as malaria, dengue, and viral encephalitides; fly-borne diseases such as leishmaniasis, bartonellosis, and sleeping sickness; and tick-associated diseases such as Rocky Mountain spotted fever, Lyme disease, and tick paralysis. Other examples include mite-borne disease such as scrub typhus, bug-borne disease as seen in Chagas' disease, and flea-borne disease as occurs in endemic typhus and the plague.³

There are five major classes of arthropods.^{4,5} The class Insecta is the largest group, although the class Arachnida, which includes ticks, spiders, and mites, is probably of greater dermatopathological interest. The class Crustacea, which includes lobsters, crabs, and shrimps, and the classes Diplopoda and Chilopoda, which include millipedes and centipedes, respectively, are not of major dermatopathological importance and are not considered in detail. They may produce local reactions at the site of contact. These include erythema, urticaria, and purpura in the case of millipedes and centipedes.⁶ A brief classification of the arthropods is given in Table 30.1. Mention should also be made of the comprehensive monograph on arthropods and the skin by Alexander⁷ and the review on venomous arthropods by Vetter and Visscher.⁸ Steen *et al.* have reviewed arthropods in dermatology.⁹

Finally, mention should be made of **Morgellons disease**, the name given by Sir Thomas Browne in 1674 to the cutaneous dysesthesia, also termed delusional parasitosis.^{10,11} Patients often present with 'fibers' or presumptive parasites removed from the skin seeking laboratory confirmation.^{12–15} It is a quite common disorder.^{16,17}

Table 30.1 A general classification of arthropods
Class crustacea
Lobsters, crabs, shrimps
Class diplopoda
Millipedes
Class chilopoda
Centipedes
Class arachnida
Scorpions
Spiders
Ticks
<i>Demodex</i>
<i>Sarcoptes</i>
<i>Cheyletiella</i>
Miscellaneous mites
Class insecta
Sucking lice (Anoplura)

Flies, mosquitoes, sandflies (Diptera)
Fleas (Siphonaptera)
Beetles (Coleoptera)
Moths and butterflies (Lepidoptera)
Bees, wasps, hornets (Hymenoptera)

ARACHNIDS

SCORPION AND SPIDER BITES

Scorpion venom may produce throbbing indurated lesions at the site of attack, usually on acral parts. Erythema, purpura, bullae, necrosis, ulcers, lymphadenitis, and systemic symptoms may develop.⁴

Local necrosis may be produced at the site of spider bites; in some cases – for example, following the bite of a black widow spider (usually *Latrodectus mactans*) – severe systemic symptoms and even death may result.¹⁸ The genus *Loxosceles* (which includes the brown recluse spider *Loxosceles reclusa*) may produce a local lesion with quite extensive necrosis, hemorrhage, blistering, and ulceration.^{19–25} This has been called 'necrotizing arachnidism'.^{26,27} Not all necrotic lesions on exposed areas are spider bites.²⁸ A chronic pyoderma gangrenosum-like reaction has also been reported.^{29,30} The diagnosis of loxoscelism can be made by swabbing the lesion and using a specific enzyme-linked immunosorbent assay to detect the venom.³¹ A diagnosis of loxoscelism is rarely based on the identification of the spider.³² Less severe reactions, such as erythema and edema, are more usual with other species of spiders.³³ Sometimes spider leg spines may dislodge in the skin, producing a mild erythematous response.³⁴ An excellent review of spider bites has been published by Wong and colleagues.³⁵ Several cases of acute generalized exanthematous pustulosis have followed spider bites.^{36,37} There is also a report of erythema multiforme induced by a spider bite.³⁸

The efficacy of various treatments for the brown recluse spider venom has been trialed using a rabbit model. No change in eschar size was produced by any of the treatments used.³⁹ Tetracyclines may be useful in treating cutaneous loxoscelism.⁴⁰

Histopathology

The appearances change from a neutrophilic vasculitis with hemorrhage, through a phase with arterial wall necrosis, to eschar-covered ulceration and subcutaneous necrosis.¹⁹ There are usually eosinophils in the accompanying inflammatory infiltrate. The term 'necrotizing arachnidism' is given to the necrotic lesions produced by some spider bites (Fig. 30.1).^{41–43}

The systemic reaction that uncommonly follows the bite of *Loxosceles reclusa* is a necrotizing vasculitis with red cell extravasation but no epidermal necrosis.⁴⁴

TICK BITES

Ticks are blood-sucking arachnids that attach to many vertebrates. They are important as hosts and transmitters of a wide range of diseases.^{45,46} After the mosquito, they are the second most common vectors of human infectious diseases in the world.⁴⁷ Their salivary secretions may produce systemic toxemia, and their embedded mouthparts may produce a local erythematous lesion or a more persistent granulomatous or nodular response.⁴⁸ Unusual reactions include panniculitis,⁴⁹ localized alopecia,⁵⁰ papular urticaria, bullae, and hemorrhage. Tick-bite anaphylaxis also occurs.⁵¹ There are two major families of ticks – soft ticks (Argasidae) and hard ticks (Ixodidae). More than 90 species of ticks, both hard- and soft-bodied varieties, have been identified in Australia.⁵² Soft ticks (*Ornithodoros* species)⁵³ are generally not perceived by the victim, whereas hard ticks – of which there are several genera, including *Ixodes*, *Amblyomma*, and *Dermacentor* – are eventually noticed because they remain attached for days and slowly engorge with blood. *Amblyomma americanum*, the lone star tick, is the most common species of this genus found in the United States.⁴⁷ Infestation by large numbers of *Amblyomma testudinarium* larval ticks has been reported.⁵⁴ Attempts to remove the tick may cause the embedded mouthparts to separate and remain in the tissue.

Figure 30.1 (A) Necrotizing arachnidism. (B) There is epidermal and superficial dermal necrosis. **(C)** Findings of necrotizing vasculitis are identified; the infiltrate contains neutrophils and eosinophils. (H&E)

Figure 30.2 A tick in situ. (H&E)

Successful removal of all parts of a tick is vital to minimize significant medical consequences.⁵² Multiple pruritic papules due to the partially burrowed larvae of the lone star tick are rarely reported.^{47,55}

Histopathology

In acute lesions, there is an intradermal cavity, below which the mouthparts may be seen (**Fig. 30.2**). Mouthparts contain a thick hyaline structure representing the chitinous wall of the hypostome; this structure contains barb-like projections that act as an anchor during feeding.⁵⁶ There is often a tract of 'necrosis' on either side, and in the first few days intense extravasation of fibrin may be seen in relation to vessels.⁴⁸ Fibrin thrombi are sometimes present in dermal capillaries.⁵⁷ This pattern of hyaline thrombi has been likened to type I (monoclonal) cryoglobulinemia.^{58,59} A moderately dense, predominantly perivascular infiltrate of neutrophils, lymphocytes, plasma cells, and histiocytes is present, with a variable admixture of eosinophils.⁶⁰ Neutrophils are sometimes prominent in recent bites. A reaction resembling erythema elevatum diutinum (also interpreted as localized chronic fibrosing vasculitis) followed a tick bite in one individual.⁶¹ The diagnosis may be difficult if tick mouthparts are not seen (**Fig. 30.3**). A panniculitis, with a preponderance of neutrophils in the infiltrate, may occur.⁴⁹

In chronic persistent lesions, there is a diffuse superficial and deep infiltrate that includes all the cells found in acute lesions but usually with many fewer neutrophils and more lymphocytes (**Fig. 30.4**). Cutaneous lymphoid hyperplasia, either of the T-cell or the B-cell type, may develop.⁵⁰ There may be occasional giant cells, dermal fibrosis, and even granuloma formation.⁶² The epidermis may show acanthosis or pseudoepitheliomatous hyperplasia.

Erythema chronicum migrans (Lyme disease), which follows the bite of *Ixodes*, has been shown to be caused by a spirochete transmitted by the tick.⁶³ It is considered with other spirochetal diseases in Chapter 24 (p. 680).

Dermoscopy can be useful both in diagnosing tick bites and in determining the species of the tick.^{64,65}

DEMODICOSIS

Two species of follicle mites are found as normal inhabitants of human skin:^{66–77} *Demodex folliculorum* lives mainly in the hair follicles and *Demodex brevis* in the sebaceous glands. The larger of the two, *D. folliculorum*, measures approximately 0.4 mm in length. Mites of this species are often aggregated in a follicle, whereas *D. brevis* is usually solitary.⁶⁸ The mites have been found in 10% of routine skin biopsies

Figure 30.3 (A) A tick-bite reaction. (B) Mouthparts are present in the dermis. (C) Another case with a granulomatous reaction to a retained tick. (H&E)

(from all sites) and in 12% of all follicles examined in these same biopsies.⁶⁹ They are common in basal cell carcinomas removed from the eyelids.⁷⁸ They are not increased in pregnancy.⁷⁹ The face is most often involved, although *D. brevis* has a wider distribution.⁷⁵ Genital lesions are rare.⁸⁰ Although increased numbers of mites are found in sections of rosacea and in subclinical forms of folliculitis, this does not prove a causal relationship.^{81–83} It is generally accepted that *Demodex*

Figure 30.4 A persistent tick-bite reaction. The appearances resemble other persistent arthropod bite reactions. (H&E)

mites are not etiologically involved in the usual form of rosacea, although they may possibly play a role in the granulomatous form, in which extrafollicular mites are sometimes seen. *Demodex* may produce a blepharitis⁷⁰ and so-called ‘rosacea-like’ demodicosis.^{74,84–88} A particularly crusted variant of rosacea-like demodicosis has been reported in an HIV-positive patient.⁸⁹ Scalp demodicosis (demodicidosis) mimicking favus has been reported in a child.⁹⁰ *Demodex* has been incriminated as a cause of localized pustular folliculitis of the face,^{71,86,91,92} facial plaques,⁹³ and of a more widespread eruption in patients with an immunosuppressed state.^{94–98} Refractory *Demodex* folliculitis may also occur in children with leukemia.⁹⁹ However, mite density is not always increased in immunosuppressed patients.^{88,100,101} They are increased in hemodialysis patients, but the increase is not statistically significant.¹⁰² Mite density is increased in patients receiving phototherapy.¹⁰³ The mites themselves may produce local immunosuppression, allowing them to survive.¹⁰⁴ This theory is based on the finding that *Demodex* mites appear to increase lymphocyte apoptosis in infested skin.¹⁰⁴ Recently, a rosacea-like demodicosis was reported as a complication of the use of pimecrolimus for the treatment of seborrheic dermatitis.¹⁰⁵ Otophyma is a rare complication of rosaceous lymphedema of the ear associated with *Demodex* infestation.¹⁰⁶

Facial erythema with follicular plugging (**pytriasis folliculorum**) is another manifestation of *Demodex* infestation.¹⁰⁷ The third clinical form of demodicosis in humans, **demodicosis gravis**, presents a clinical picture similar to that of severe granulomatous rosacea.¹⁰⁸

Histopathology

The effects of *Demodex* infestation include follicular dilatation, the presence of dense homogeneous eosinophilic material surrounding the mites, folliculitis,¹⁰⁹ and perifollicular chronic inflammation (**Figs. 30.5 and 30.6**). Tiny follicular spicules resulting from the combination of follicular hyperkeratosis and protruding mites have been reported (**Fig. 30.7**).^{110,111} There are several reports of a granulomatous reaction to extrafollicular *Demodex*, usually in granulomatous or pustular rosacea.^{72,73} In demodicosis gravis, there are many dermal granulomas containing mite remnants partly phagocytosed by foreign body giant cells. There may also be central necrosis.¹⁰⁸

In rosacea-like demodicosis, up to 10–15 *D. folliculorum* may be found in individual follicles.⁷⁴ Telangiectasia of superficial vessels,

Figure 30.5 A *Demodex* mite in the lower sebaceous duct. (H&E)

Figure 30.6 *Demodex* perifolliculitis. There are numerous mites in the follicle. (H&E)

Figure 30.7 Pityriasis (*Demodex*) folliculorum. *Demodex* mites protrude from hair follicles producing small 'spicules' on the surface. (H&E)

perifollicular granulomas, and mild perivascular chronic inflammation may also be seen in this condition. In the crusted variant seen in an HIV-positive patient, there were mixed perifollicular infiltrates and *Demodex* fragments adjacent to hair follicles.⁸⁹

Dermoscopy has shown 'tails' (whitish threads representing organisms protruding from follicular openings), dilated follicular orifices, and, in inflammatory disease, reticular dilated blood vessels oriented horizontally.¹¹²

Differential diagnosis

A recent case of facial erythema in a patient who had undergone allogeneic bone marrow transplantation for acute lymphoblastic leukemia raised the question of late-onset graft-versus-host disease, chemotherapy reaction, phototoxicity, other acneiform eruptions, or a lupus erythematosus-like reaction. Histopathology, however, showed characteristic features of *Demodex* folliculitis and lacked the keratinocyte apoptosis and satellite cell necrosis of graft-versus-host disease or the epidermal dysmaturation and interface changes associated with chemotherapy reactions.¹¹³

SCABIES

Scabies is a contagious disease caused by the mite *Sarcoptes scabiei* var. *hominis*. It is acquired particularly under conditions of overcrowding and poor personal hygiene or during sexual contact.^{114,115} Scabies was present in 8.8% of the population in a Brazilian slum.¹¹⁶ Patients with both minimal disease and only a few mites¹¹⁷ and exaggerated atypical lesions complicating AIDS^{118–123} are now being seen, as are patients with inherited disorders of keratinization.¹²⁴ The disease tends to appear in epidemics, which have a cyclical character, recurring at intervals of approximately 30 years and lasting for approximately 15 years.¹²⁵ The reasons for these cyclic fluctuations are not understood. A new cycle probably commenced in 1993, although there are conflicting reports on the date of commencement of this most recent cycle.¹²⁶ Infections are more frequent in the cooler months of the year, possibly related to host overcrowding.¹²⁷

Three clinical forms are found: papulovesicular lesions, persistent nodules, and Norwegian (crusted) scabies. The usual lesions are *papules* and *papulovesicles* that are intensely pruritic. The vesicles are usually found at the end of very fine wavy dark lines, best seen with the help

Figure 30.8 *Sarcoptes* mite. (×100)

of a hand lens or by applying a small amount of ink to the surface and removing the excess.¹²⁸ These lines represent the excreta-soiled burrows in the horny layer in which the female travels to deposit her eggs. Epiluminescence microscopy enhances the diagnosis of scabies; it gives a low number of false-negative results.^{129,130} Amplification of *Sarcoptes* DNA in the cutaneous scale, using polymerase chain reaction, has been used to confirm inapparent infection.¹³¹ The application of cyanoacrylate glue (Super Glue®) to the skin, followed by a glass slide that is pressed on the suspect skin site, is a recently described method for mite identification.¹³²

The female mite measures up to 0.4 mm in length and rather less in breadth, whereas the adult male, which dies after copulation, is much smaller (Fig. 30.8). The sites most commonly affected are the interdigital skin folds, the palmar surfaces of the hands and fingers, the wrists, the nipples, the inframammary regions, and the male genitals. The vulva is a rare site.¹³³ A more generalized eruption is sometimes seen in infants and young children;¹³⁴ misdiagnosis is common in this group.^{135–137} In addition to the burrows, there is nearly always a secondary rash of small urticarial papules with no mites, which may result from autosensitization.^{138,139} Bullae, resembling bullous pemphigoid, are rarely seen.^{140–144} The presence of circulating antibodies against BP180 and/or BP230 suggests that scabies may induce true bullous pemphigoid.¹⁴⁵

In approximately 7% of patients, particularly children and young adults, reddish-brown pruritic nodules develop, with a predilection for the lower trunk, scrotum, and thighs.¹²⁵ These lesions may persist for a year, despite treatment. Mites are rarely found, and this form (*persistent nodular scabies*) is thought to represent a delayed hypersensitivity reaction similar to that found following some other arthropod bites.

Norwegian (crusted) scabies is a rare contagious form consisting of widespread crusted and secondarily infected hyperkeratotic lesions, found in the mentally and physically debilitated,^{146–148} as well as in immunosuppressed patients.^{123,149–158} This form has also been reported in an otherwise healthy pregnant woman¹⁵⁹ and in a healthy infant.¹⁶⁰ Norwegian scabies also occurs in patients with epidermolysis bullosa^{161,162}

Figure 30.9 Scabies. There are spongiotic vesicles containing many eosinophils. (H&E)

and in neurological disorders with sensory impairment.¹⁶³ There is an extremely heavy infestation with mites. Longitudinal nail splitting has been reported as a consequence of crusted scabies.¹⁶⁴

Human infestation with varieties of *Sarcoptes scabiei* of animal origin is not uncommon.¹⁶⁵ They produce a self-limiting disease without the presence of burrows.^{166,167} These animal variants are morphologically indistinguishable from the human variant of *S. scabiei*.

The conventional antiscabietics have poor compliance; however, ivermectin, an oral scabicide, is proving a useful substitute.^{168–170} Tea tree oil, derived from *Melaleuca alternifolia*, has been found to possess acaricidal activity *in vitro*.¹⁷¹

Immunological features

There is evidence that immunological phenomena are involved in scabies.^{172–174} Immediate hypersensitivity may result in the primary lesions, and delayed hypersensitivity may result in the persistent nodular lesions. Elevated levels of IgE have been found in the serum of some patients with scabies, but the serum IgA is reduced in many with the Norwegian form.^{175,176} IgE has been demonstrated by immunofluorescence in vessel walls in the dermis,¹⁷⁷ IgA and C3 in the stratum corneum, and IgM and/or C3 along the basement membrane in some cases.¹⁷⁸ IgE-containing plasma cells have been found in nodular lesions.¹⁷⁹ In crusted (Norwegian) scabies, there is a predominance of skin-homing cytotoxic (CD8⁺) T cells and a lack of B cells, leading to a defective immune response. This results in uncontrolled growth of the parasite.¹⁸⁰

Histopathology

The histological changes are sufficiently distinctive at least to suggest the diagnosis.¹⁸¹ There is a superficial and deep infiltrate of lymphocytes, histiocytes, mast cells,¹⁸² and eosinophils, together with some interstitial eosinophils. These features are common to many arthropod reactions. Flame figures and a vasculitis are found rarely.^{183,184} Langerhans cell hyperplasia may be a significant finding in biopsies of scabetic lesions.¹⁸⁵ In addition, there are spongiotic foci and spongiotic vesicles within the epidermis, with exocytosis of variable numbers of eosinophils and sometimes neutrophils (Fig. 30.9). Subepidermal bullae, resembling bullous pemphigoid, have been reported.^{140,142} Eggs, larvae, mites, and excreta may be seen in the stratum corneum if an obvious burrow is excised (Fig. 30.10).^{186,187} Pink 'pigtales', connected to the stratum corneum and representing egg fragments or casings left behind after the mite hatches, may be present.¹⁸⁸ Polarization microscopy may

Figure 30.10 Scabies. (A) A burrow is present in the stratum corneum. A mite is present at one end with a trail of debris. (B) A higher power view of the mite. (H&E)

also be helpful in recognizing elements of organisms and their products; thus, the spines of mites have a central dark core and peripheral birefringence, whereas fecal matter (scybala) shows stippled peripheral birefringence.¹⁸⁹ If the secondary (autosensitization) lesions are biopsied, the picture may not be diagnostic: no mites will be seen, and there is a report which suggests that even eosinophils may be absent.¹³⁸ Older lesions may simply show excoriation and overlying scale crusts.¹⁸¹ Mites may be found in association with cutaneous tumors, either as an incidental phenomenon or as part of a more widespread infestation.¹⁹⁰

The lesions of persistent nodular scabies resemble those of other persistent bite reactions, with a more dense superficial and deep inflammatory cell infiltrate that includes lymphocytes, macrophages, plasma cells, eosinophils, Langerhans cells, and sometimes atypical mononuclear cells (Fig. 30.11).^{186,191} Lymphoid follicles are sometimes present, and the infiltrate may even extend into the subcutaneous fat. Pseudoepitheliomatous hyperplasia is not a feature. Cases have been published that purportedly resembled cutaneous lymphoma, but the descriptions provided in those instances are not those of lymphoma.¹⁹² Mites are rarely found in routine sections, but if serial sections are studied, mite parts can be seen in approximately 20% of cases.¹⁹³ It has been suggested that penetration of mites into the dermis may be responsible for the inflammatory nodules of persistent nodular scabies.¹⁹⁴

In Norwegian scabies, there is a massive orthokeratosis and parakeratosis containing mites in all stages of development (Fig. 30.12). The

Figure 30.11 Persistent nodular scabies. There is a superficial and deep infiltrate within the dermis. The interstitial eosinophils are not obvious at this magnification. (H&E)

underlying epidermis shows psoriasiform hyperplasia with focal spongiosis and exocytosis of eosinophils and neutrophils, sometimes producing intraepidermal microabscesses. The dermis contains a superficial and deep infiltrate of chronic inflammatory cells and usually some interstitial eosinophils.

The eggs with developing mites and fecal material can be identified within burrows using reflectance confocal microscopy,¹⁹⁵ and recently, a larva moving freely in the skin was identified with this method.¹⁹⁶ Dermoscopy can also be useful, displaying a triangular shape (representing the head and front legs of the adult mite) and sometimes revealing the overall shape of the mite.¹⁹⁷

Differential diagnosis

In the absence of mite parts or products, the diagnosis of scabies is difficult to make, although it can be (and often is) suspected. A spongiotic vesicle with underlying eosinophil-rich dermal infiltrate could also be evidence of reaction to another type of arthropod. Multiple levels may therefore be worthwhile in an effort to find the mites. Polarization microscopy can aid in this search.¹⁸⁹ Similarly, postscabetic nodules can be mimicked by other chronic arthropod reactions, including those due to tick bite. Foci of surface necrosis, tick mouthparts, or small vessel thrombi in the dermis are clues to the diagnosis of tick-bite reaction. Crusted scabies can closely resemble psoriasis, both clinically and microscopically, but there is a myriad of organisms in the markedly hyperkeratotic stratum corneum in the former. As noted previously, lesions resembling bullous pemphigoid, both clinically and microscopically, have been reported in patients with scabies. In a few cases, direct immunofluorescence study has also shown linear or granular immunoglobulin deposits along the basement membrane zone, suggesting that mites may injure the basement membrane zone directly or possess antigens that cross-react with those of the basement membrane zone.¹⁹⁸ Development of pemphigoid lesions in unusual clinical circumstances should prompt consideration of this possible association. Patients with scabies infestation of long duration (>3 months) often have increased numbers of CD30⁺ cells in the inflammatory infiltrate.¹⁹⁹ The author misdiagnosed lymphomatoid papulosis on a superficial shave biopsy of scabies (some years ago) as a consequence of the large number of CD30⁺ cells. Hyperplasia of Langerhans cells is now a known finding in lesions of patients with scabies and should

Figure 30.12 Norwegian scabies. The thick keratin layer overlying the psoriasiform epidermis contains many mites. (H&E)

not be confused with true Langerhans cell histiocytosis.¹⁸⁵ Langerhans cell hyperplasia has also been identified in children who do not have scabies; in one instance, this was associated with presumed contact dermatitis, and in another, it was associated with pityriasis lichenoides acuta.²⁰⁰

CHEYLETIELLA DERMATITIS

Several species of *Cheyletiella*, a mite found on dogs, rabbits, and cats, can produce an intensely pruritic dermatitis in humans.^{201–203} In animals, it produces so-called ‘walking dandruff’. There are erythematous papules and papulovesicles, sometimes grouped, with a predilection for the chest, abdomen, and proximal extremities.²⁰⁴ Involved areas usually correspond to the sites of close physical contact with the infested pet.²⁰⁵ The mite is almost never found on humans, and the diagnosis may be confirmed by examining fur brushings of the patient’s pet for the mite.^{206,207} This condition is no longer thought to be synonymous with so-called ‘itchy red bump’ disease (papular dermatitis), a papular pruritic disorder of uncertain histogenesis that was originally reported from Florida (see p. 125).^{201,208} Delayed hypersensitivity

mechanisms are thought to play a role in the pathogenesis of the eruption.²⁰⁹

Histopathology

Sections show focal epidermal spongiosis at the site of the bite. There is a superficial and mid-dermal predominantly perivascular infiltrate composed of lymphocytes, macrophages, and some eosinophils. There are usually some interstitial eosinophils, suggesting an arthropod bite; however, the reaction is more superficial and less inflammatory than the usual arthropod reaction. Vesiculobullous lesions appear to result from both intraepidermal and subepidermal vesiculation, although the histology of this rare form often goes unreported.²¹⁰

OTHER MITE LESIONS

Five other families of mites have been incriminated in the production of cutaneous lesions: Tyroglyphoidea (food mites), Pyemotidae (predacious or grain itch mites), Dermanyssidae (parasitoid or rat mites), Trombiculidae (trombiculid or harvest mites, chiggers), and Tydeidae (sawdust mite).^{4,5,202,211}

Food mites and predacious mites produce erythematous papules, papulovesicles, or urticaria in workers handling certain foods and grain. The lesions may be mistaken for scabies, but there are no burrows.⁴⁸ The genera involved include *Glycophagus* (grocery mite), *Acarus* (cheese mite), *Tyrophagus* (copra mite), *Pyemotes* (grain itch mite), and *Tyroglyphus*.^{48,166,212} The house dust mite, *Dermatophagoides pteronyssinus*, and related species are widely distributed in bedding and clothing, and they may play a role in producing or exacerbating chronic dermatitis.^{213,214}

The parasitoid mites may produce papular urticaria in people employed in grain stores or living in places harboring rats.^{215,216} Pet rabbits may be infected by the mite *Listrophorus gibbus*, which can produce a papular urticaria in the handler.²¹⁷ Various birds, and also pet gerbils, may harbor mites from the family Dermanyssidae.^{218–221} The term ‘gamasoidosis’ has been used to describe the human skin disease caused by mites from birds and other animals.²¹⁸

The trombiculid mites may produce a severe dermatitis with minute, intensely pruritic red elevations.²²² They have a predilection for the lower legs, groin, and waistline. Acute superficial lymphangitis with axillary adenopathy has occurred following the bite of the pigeon mite, *Argas refluxus*.²²³

Histopathology

The lesions produced by mites other than chiggers resemble those generally seen in mild arthropod reactions, with a superficial and mid-dermal perivascular infiltrate, some interstitial eosinophils, and mild epidermal spongiosis. The mite is almost never found. Some neutrophils are usually present in lesions produced by *Pyemotes* species.⁴⁸

Bites by chiggers (*Trombicula* species) may be centered on hair follicles or in skin having a thin horny layer. A tissue canal or ‘stylostome’ surrounded by a mass of hyaline tissue runs into the malpighian layer. There is usually epidermal spongiosis, dermal edema with some neutrophils, and later a more mixed dermal inflammatory infiltrate, as in other arthropod lesions. A chronic granulomatous response has been described.⁴⁸

INSECTS

HUMAN LICE (PEDICULOSIS)

Pediculosis, which has been known for more than 10,000 years, is caused by three types of lice, each having a separate microenvironment.²²⁴ The head louse (*Pediculus humanus capitis*) infests the hairs

of the scalp. It is an increasing problem in many urban communities,¹¹⁶ with outbreaks particularly in schools,^{225–230} although the incidence is declining in some communities.²³¹ Recent work suggests that fomite transmission is an important source of infestation.^{232–234} In some areas of the world, including the United States, Canada, and Australia, public health authorities have adopted a ‘no nit’ policy that results in the immediate dismissal from school of any child found to have lice or eggs (nits) in their hair. Because not all nits are viable, and not all children with them have concurrent lice, it has been suggested that the ‘no nit’ policy be replaced with other programs.²³⁵ Because the nit sheath is similar in composition to hair, eradication programs will need to take note of this fact.²³⁶ Bug buster kits (fine-toothed combs) are favored in some regions over the use of pediculicides, such as malathion and permethrin.^{237–241} In a comparative trial, malathion was found to be superior to permethrin for the treatment of head lice.²⁴² There is an emerging resistance to pediculicides in some areas of the world.²⁴³ New pediculicides are being trialed.²⁴⁴

The pubic louse (*Phthirus pubis*) infests pubic and axillary hair in particular, although there may be colonization of any heavy growth of hair on the trunk and limbs.²⁴⁵ Occasionally, the eyebrows are infested, and very rarely the scalp is infested.^{246–249} It is more common in the cooler months.²⁵⁰ The HIV status of the patient does not appear to influence the severity of the infestation. Both the pubic louse and the head louse cement their eggs to hair, forming the minute gritty projection that is known as a nit. Multiple bluish spots (maculae ceruleae) may be found, particularly on the trunk, in persons infested with the pubic louse.²⁵¹

The body louse (*Pediculus humanus corporis*) divides its existence between the host and the host’s clothing, in the seams of which it deposits its eggs.

The lice are bloodsuckers, but the amount consumed is minimal.²⁵² The injected saliva may produce an allergic reaction. This hypersensitivity rash, or pediculid, may mimic a viral exanthem.²²⁴ The resulting itching may lead to excoriation or secondary bacterial infection.

Histopathology

A louse may be removed from the body and examined microscopically for confirmation (Fig. 30.13). Nits may also be identified by examining involved hairs (Fig. 30.14).

Scanning electron microscopy of the egg of the pubic louse has found that the egg is totally encased by a proteinaceous sheath, except for the operculum, through which oxygen exchange occurs.²⁵³ The operculum is the target of topical insecticides for ovicidal kill.²⁵³

BEDBUGS

Bedbugs (Cimicidae) are found usually in dirty and dilapidated housing, associated with unwashed bed linen.²⁵⁴ They may also infest wooden seating in public transport. They are notoriously difficult to eliminate.²⁵⁵

The common bedbug (*Cimex lectularius*) can produce pruritic, urticarial, vesicular, and even bullous lesions.^{256,257} Anaphylactic reactions and persistent nodular lesions are rare.²⁵⁸ The distribution of the lesions is influenced by the method of infestation and the wearing of bedclothes.²⁵⁵ At least six other species may rarely parasitize humans.²⁵⁹

Histopathology

Urticarial lesions show variable edema of the upper dermis with perivascular lymphocytes, eosinophils, and mast cells. A few interstitial eosinophils are also present. Vesiculobullous lesions show both intraepidermal and subepidermal edema. Hemorrhage may be present in the dermis in bullous lesions.²⁵⁵

Figure 30.13 Crab louse (*Phthirus pubis*). (×27)

Figure 30.14 Pediculosis. Hair shaft with an attached egg (nit) of the head louse. (×40)

MYIASIS

Myiasis is the infestation of live human tissues by the larvae of flies in the order Diptera.^{260–263} It is said to be the fourth most common travel-associated skin disease.^{264,265} In Central and South America, dermal myiasis is usually caused by the ‘human botfly’, *Dermatobia hominis*.^{266–273} In West and Central Africa, the tumbu fly (*Cordylobia anthropophaga*) is involved.^{274–280} In one study of a rural community in the Niger Delta, 36% of 150 women and 20% of 75 infants studied were infected by *C. anthropophaga*.²⁸¹ Other flies, some of them of restricted geographical distribution, can produce myiasis, including species of *Parasarcophaga*,²⁸² *Psychoda*,²⁸³ *Gasterophilus*, *Hypoderma*,^{284,285} *Cuterebra*,^{286–290} *Cochliomyia*,^{291–293} *Chrysomya*,²⁹⁴ and *Wohlfahrtia*.^{4,295} The larvae of the common housefly, *Musca domestica*, may rarely infest the skin of debilitated and extremely neglected patients.^{296,297} The eggs may be transmitted to humans by another insect, such as the mosquito in the case of *D. hominis*, or the larvae may burrow into the skin of a suitable host after hatching on the ground or on clothing, as with the tumbu fly.²⁹⁸ In contrast to botfly larvae that are larger and have abdominal hooklets anchoring them under the skin, the tumbu larvae do not have anchoring hooklets and they can be extruded by squeezing the skin.²⁹⁸

The larva completes its molts in approximately 2 weeks to 3 months or longer, depending on the species. It then works its way out of the skin and falls to the ground, where pupation occurs. This may be noted by the patient.

The lesions have a predilection for exposed surfaces such as the feet and forearms.²⁹⁹ The scalp is uncommonly involved, whereas penile involvement is very rare.^{279,300,301} Gingival myiasis has been reported; predisposing conditions include poor dental hygiene, mouth breathing, and other factors.³⁰² Lesions have a furuncle-like presentation that culminates in ulceration.^{264,303,304} Sometimes there are plaques with draining sinuses.³⁰⁵ Tissue destruction may result when sites such as the nose are involved.²⁹³ Large inflammatory nodules have been reported in a person with HIV infection.³⁰⁶ There may be throbbing pain as the lesion enlarges. Ultrasound and dermoscopy can be used to confirm the clinical diagnosis.^{307,308}

Myiasis has been proposed as a risk factor for prion diseases in humans.³⁰⁹ Prion rods have been identified in both fly larvae and pupae.³⁰⁹

Treatment may involve three processes: occlusion to deprive the larva of oxygen, removal of the larva by squeezing or a surgical technique, and the use of larvicides such as ivermectin.²⁶³

Histopathology

There is usually a small cavity, in the dermis and sometimes in the subcutaneous tissue, containing the developing larva (Fig. 30.15). Surrounding this is a heavy mixed inflammatory cell infiltrate that includes lymphocytes, histiocytes, occasional foreign body giant cells and plasma cells, as well as eosinophils; neutrophils are also present near the cavity.²⁶⁰ There are abundant activated fibroblasts elaborating collagen, which may relate to larval containment.²⁶⁰ A sinus tract may lead to the surface, with ulceration. Fragments of larva are usually seen within the cavity (Fig. 30.16). It is encased by a thick chitinous cuticle with widely spaced spines on the surface. These spines act as anchoring points to fasten the larva to the skin.³¹⁰ This material is polarizable.³¹¹ Beneath the cuticle, layers of striated muscle and internal organs may be seen.³¹²

Immunohistochemical studies have shown that 30% of the cells in the inflammatory infiltrate are cytotoxic CD4⁺ T cells that produce a Th2 cytokine pattern.³¹³

Dermoscopy of the posterior aspect of a *D. hominis* larva shows breathing spiracles resembling bird's feet and peripheral black dots resembling a 'thorn crown'.³¹⁴

TUNGIASIS

Tungiasis is produced by infestation of the skin by the pregnant female sand flea *Tunga penetrans*.³¹⁵ It occurs in Central and South America, tropical Africa, and Pakistan.^{316–320} In one community in Nigeria, 45% of the population were found to be infested with this parasite, and the median parasite load was six.³²¹ Close to 100 parasites have been detected in a patient with Klippel–Trenaunay syndrome.³²² International travel has resulted in its occurrence in many countries.^{323–329} Because the flea is a poor jumper, lesions are usually found on the feet.³²¹ Penetration into the dermis by the flea produces characteristic single or multiple white papules and eventually nodules approximately 1 cm in diameter.³³⁰ Lesions have a central black dot and erythematous margins. The black region corresponds to the posterior portion of the flea.³³¹ Dermoscopy can be used to confirm the diagnosis.^{332–334} On entering the skin, the female tunga is approximately 0.1 cm in diameter, but this increases to 0.6 cm or more as the 150–200 eggs within the abdomen of the gravid female mature. Once the ova have been shed through an opening in the skin and the tunga has died, the nodule usually becomes frankly ulcerated.

A second species of *Tunga*, *T. trimamillata*, has been reported in humans from Ecuador.³³¹ Its preferential hosts are goats, pigs, and cattle.

Surgical removal of the sand flea is the treatment of choice. Topical ivermectin, thiabendazole, and metrifonate have been used. Oral ivermectin is also effective.³³⁵

Figure 30.15 Myiasis. Larval parts are present within a subcutaneous cavity, the wall of which contains a heavy inflammatory cell infiltrate. (H&E)

Histopathology

The diagnosis is made by finding the *Tunga* in the epidermis or dermis, with its characteristic exoskeleton and internal parts, including ova (Fig. 30.17).^{330,336} The most commonly identified organs are the eosinophilic cuticle, eggs in different stages of development, and tracheal rings.³³⁷ The epidermis shows parakeratosis, acanthosis, spongiosis, and basal cell hyperplasia.³³⁷ There is a surrounding mixed inflammatory cell infiltrate of lymphocytes, plasma cells, and eosinophils. A mass of eggs may be seen within the stratum corneum, with underlying epidermal necrosis; in later lesions, there is ulceration.³³⁰

Dermoscopy can be an aid to diagnosis. The lesions show an annular brown or white ring with a central black pore; *ex vivo* examination of the organism shows the flea head, sometimes accompanied by a distended 'jelly sac' abdomen containing eggs.^{338,339}

OTHER INSECT BITES

Species within the order Diptera may be responsible for cutaneous lesions other than myiasis. These insects include mosquitoes, gnats,

Figure 30.16 Myiasis (*Dermatobia hominis*). (A) The larva has curved contours, with an external cuticle and abundant striated muscle. (B) Higher magnification demonstrating the organism's exterior spines. (H&E)

and midges. Mosquitoes may cause urticarial and even bullous lesions in occasional sensitized hosts. They may also cause a life-threatening disorder in patients with Epstein–Barr virus infection (see later).^{340,341} The biting gnats and midges may give urticarial wheals or pruritic papules.³⁴² Papular urticaria is a common reaction to fleas. Large persistent lesions may develop in patients infected with HIV.³⁴³ A related phenomenon is the development of exuberant lesions in patients with hematological disorders, particularly chronic lymphocytic leukemia (see later).

Beetles (order Coleoptera) can produce slowly forming blisters, necrotizing lesions, or papular urticaria.^{344–346} The best known blister beetle is *Lytta vesicatoria* (the Spanish fly), an insect endemic to southern Europe.³⁴⁷ The blisters are produced by cantharidin, a substance found in certain beetles.³⁴⁸ Other families of beetle have a different vesicating toxin in their coelomic fluid, known as pederin, which is released when the beetle is accidentally crushed on the skin.³⁴⁹ In 2000, an outbreak of more than 250 cases of a vesicular dermatitis was reported from Australia.³⁴⁷ It was caused by the genus *Paederus*

Figure 30.17 Tungiasis. (A) The parasite has penetrated the epidermis and occupies much of the dermis. (B) A further case of the disease. (H&E)

(rove beetles).³⁴⁷ Other outbreaks have been reported from Sri Lanka,³⁵⁰ south India,³⁵¹ and Iran.³⁵²

Some species of moths and butterflies (order Lepidoptera) have larvae (caterpillars) with surface hairs (setae) that may produce urtication on entering the skin. The setae, which contain an urticating toxin (thaumetopoein), may be airborne, producing disease in unsuspecting hosts.^{353,354} Erythematous macules and papules and urticarial wheals

may be seen.^{355–357} Incidentally, there are more than 165,000 species in the order Lepidoptera, but only 150 are medically important.³⁵⁸

Moths of the genus *Hylesia* (found particularly in South America) may produce an intensely pruritic urticarial rash within a few minutes to several hours after contact with the abdominal hairs of the adult female moth.³⁵⁹

Small erythematous papules may result from the bite of the thrip, a tiny insect in the order Thysanoptera.³⁶⁰ They are often misdiagnosed as mosquito bites. They may also produce itching without visible lesions.³⁶¹ Psocids, very small insects of the order Psocoptera, very rarely cause infestations of humans.³⁶² One such genus, *Liposcelis*, is found in old, moldy books and called ‘book lice’. They may cause mild pruritus.³⁶² One case of infestation associated with onychomycosis has been reported.³⁶³

Severe urticarial edema and even anaphylaxis may follow the stings of species within the order Hymenoptera (bees, wasps, ants, and hornets) in some susceptible individuals.^{3,364–366}

Unusual complications following insect bites include a compartment syndrome in pediatric patients³⁶⁷ and necrotizing fasciitis (and death) following an insect bite.³⁶⁸

The cutaneous side effects of insect repellents have been reviewed.³⁶⁹ Despite the widespread use of repellents, complications, such as an irritant contact dermatitis, are quite uncommon.³⁶⁹

Histopathology

The appearances depend on many factors, such as the nature of the arthropod, the duration of the lesion, the immunological reaction (immediate or delayed hypersensitivity), the presence of arthropod parts, and the discharge of toxins.

Lesions of papular urticaria show prominent papillary dermal edema and a superficial and deep inflammatory infiltrate, with perivascular accentuation and usually some interstitial eosinophils. Papular and papulovesicular lesions resemble those produced by other arthropods.

Some neutrophils are often present in lesions biopsied in the first day or so, particularly with certain insects. Flea bites usually have some neutrophils in the exudate, as do the necrotizing lesions produced by beetles.

Plasma cells may be prominent, particularly in the deep dermis, in some persistent insect bites; rarely, the appearances may simulate a plasmacytoma.

Focal epidermal necrosis is seen with some gnat and beetle bites.^{342,346,370} The vesicular dermatitis associated with the whiplash rove beetle (*Paederus*; see p. 107) is characterized by intraepidermal and suprabasal vesicles and pustules with reticular and confluent necrosis of the epidermis and the superficial zones of the appendages (Fig. 30.18).³⁴⁷ There are occasional eosinophils in the dermal infiltrate.

Bullous lesions seen in some hosts susceptible to mosquitoes have large intraepidermal vesicles with thin strands of epidermis between the vesicles and prominent edema of the papillary dermis (Fig. 30.19).³⁷¹ Intraepidermal vesicles containing eosinophils may be seen in caterpillar dermatitis and in some other bite reactions, particularly at the point of entry of any mouthparts. Moths of the genus *Hylesia* produce a spongiotic epidermal reaction related to a fine hair shaft implanted by the moth; there is some exocytosis of neutrophils and lymphocytes.

Other findings that may be seen in persistent insect bite reactions include pseudoepitheliomatous hyperplasia, sometimes quite severe (Fig. 30.20), and atypical dermal infiltrates that may be mistaken for malignant lymphoma.^{372,373} CD30⁺ cells may be present, as also occurs in scabies.³⁷⁴ Langerhans cells, particularly in a perivascular location, are sometimes abundant in bite reactions. The dendritic staining pattern of these cells with CD1a helps to differentiate them from Langerhans cell histiocytosis.³⁷⁵ The presence of a heterogeneous cell

Figure 30.18 *Paederus* bite reaction. A neutrophilic spongiosis with focal necrosis is present. (H&E) (Photograph kindly provided by Dr Dominic Wood)

population with interstitial eosinophils is a reassuring sign in these rare atypical lesions.

Note that the cnidarians (coelenterates) can produce lesions that mimic both clinically and histologically those produced by arthropods (see p. 758), including the development of persistent nodular lesions.

EXAGGERATED BITE REACTIONS

Exuberant papular and vesiculobullous lesions may develop in patients with leukemia, particularly chronic lymphocytic leukemia, apparently as an exaggerated response to arthropod bites.^{376–378} A similar reaction has been reported in association with mantle cell lymphoma.^{379,380} Patients usually do not recall being bitten. The reaction may precede the diagnosis of the hematological disorder. Lesions may persist for many years.³⁷⁷ Immunodeficiency may play a role in their pathogenesis because similar lesions have been reported in HIV infection (discussed previously). It has been suggested that the term *eosinophilic dermatosis of myeloproliferative disease* is more appropriate.^{381,382}

Dapsone has been used successfully in the management.³⁸³

Histopathology³⁷⁶

The epidermal changes include eosinophilic spongiosis, vesiculation, and full-thickness necrosis. Both intraepidermal and subepidermal vesicles may be present (Fig. 30.21). There is a superficial and deep perivascular and interstitial infiltrate of lymphocytes and eosinophils of variable density. Flame figures and lymphoid nodules are sometimes seen (Fig. 30.22). A vasculitis, usually of lymphocytic type, may be present.

Insect bite-like reactions have also occurred, either simultaneously or sequentially, in association with eosinophilic panniculitis (in a patient with chronic lymphocytic leukemia)³⁸⁴ and with eosinophilic cellulitis (in a patient with diffuse large B-cell lymphoma).³⁸⁵

MOSQUITO HYPERSENSITIVITY

The triad of hypersensitivity to mosquito bites, chronic Epstein–Barr virus infection, and natural killer cell leukemia/lymphoma has been reported in recent years, mainly in Japanese children.^{340,386–388} Some patients may not express the triad; patients with natural killer cell lymphocytosis have been reported with mosquito hypersensitivity.³⁴¹ Death from the hemophagocytic syndrome may occur.³⁴⁰

Figure 30.19 Arthropod bite reaction. (A) Mixed epidermal and subepidermal edema are present. (B) A further case with only subepidermal edema. (H&E)

Figure 30.20 Arthropod bite reaction. There is pronounced pseudoepitheliomatous hyperplasia, an uncommon pattern of reaction. (H&E)

Figure 30.21 Exaggerated bite reaction in a patient with chronic lymphocytic leukemia. (H&E)

Figure 30.22 Exaggerated bite reaction. There are numerous eosinophils and flame figures. (H&E)

Hypersensitivity to mosquito bites, presenting as a hydroa vacciniforme-like eruption in patients with lymphoma, is a closely related phenomenon.³⁸⁹ Such patients may not have chronic Epstein–Barr virus infection (EBV).³⁸⁹

Histopathology

The epidermis is usually necrotic. There is underlying dermal edema, particularly in the superficial dermis. There is a leukocytoclastic vasculitis. In addition to the infiltration of neutrophils, there are also many lymphocytes. They are large, having irregularly shaped nuclei, and express CD56.³⁸⁹ *In situ* hybridization with the *EBER1* probe shows that approximately 5% of infiltrating cells in the skin lesions are positive for EBV.³⁸⁷

Acanthomas	789	Erythroplasia of Queyrat	803	Callus	827
Epidermolytic acanthoma	790	Intraepidermal epithelioma (Jadassohn)	804	Onychopapilloma	827
Warty dyskeratoma	790	Malignant tumors	804	Onychomatrixoma	828
Acantholytic acanthoma	790	Basal cell carcinoma	804	Keratoacanthoma	828
Seborrheic keratosis	790	Nevoid basal cell carcinoma syndrome	814	Giant keratoacanthoma	829
Leser–Trélat sign	793	Squamous cell carcinoma	815	Abortive keratoacanthoma	829
Dermatosis papulosa nigra	793	Spindle cell squamous carcinoma	817	Keratoacanthoma centrifugum marginatum (multinodular keratoacanthoma)	829
Melanoacanthoma	793	Adenoid squamous cell carcinoma	818	Subungual keratoacanthoma	829
Clear cell acanthoma	794	Pseudovascular squamous cell carcinoma	818	Multiple keratoacanthomas	829
		Other variants of squamous cell carcinoma	818		

INTRODUCTION

Tumors of the epidermis are a histopathologically diverse group of entities that have in common a localized proliferation of keratinocytes resulting in a clinically discrete lesion. They may be divided into a number of categories, reflecting their different biological behaviors. These include hamartomas (epidermal nevi), reactive hyperplasias (pseudoeplitheliomatous hyperplasia), and benign tumors (acanthomas), as well as premalignant, *in situ*, and invasive carcinomas. There is a tendency in some countries to regard the epidermal dysplasias as squamous cell carcinoma *in situ* and to include keratoacanthoma as a variant of squamous cell carcinoma despite its different biological potential.

EPIDERMAL AND OTHER NEVI

Some authors use the term 'epithelial nevus' or 'epidermal nevus' as a group generic term to cover malformations of adnexal epithelium as well as those involving the epidermis alone (see later).^{1,2} The term 'epidermal nevus' is used here in a restricted sense and does not include organoid, sebaceous, eccrine, and pilar nevi. These are considered with the appendageal tumors in Chapter 33. An exception has been made for nevus comedonicus, an abnormality of the infundibulum of the hair follicle. It is considered here because its histological appearance suggests an abnormality of the epidermis rather than of appendages. Furthermore, the report of the coexistence of nevus comedonicus and an epidermal nevus suggests that the two entities are closely related.³ The nevus comedonicus syndrome is regarded as a variant of the epidermal nevus syndrome; it has also been grouped with the organoid nevus (see p. 951).

EPIDERMAL NEVUS

The nomenclature of epidermal nevi has become confusing, with some authors using the term as a group generic expression to cover all hamartomatous lesions derived from epidermal components, and resulting from mutations in early embryonic stages of development. They are then subclassified on the basis of their main constituent. The term 'epidermal nevus', as used here, is called keratinocyte epidermal nevus (OMIM 162900) in this new system.⁴ Some cases have several components (keratinocyte, sebaceous, and eccrine), highlighting the difficulties created by this new nomenclature.⁵

An epidermal nevus is a developmental malformation of the epidermis in which an excess of keratinocytes, sometimes showing abnormal maturation, results in a visible lesion with a variety of clinical and histological patterns.⁶ They are hamartomatous lesions with an incidence of approximately 1 in 1000 live newborns.⁷ Such lesions are of early onset, with a predilection for the neck, trunk, and extremities.^{8,9} Intraoral lesions have been reported.¹⁰ There may be one only, or a few small warty brown or pale plaques may be present. A facial variant that was bilateral and symmetric has been reported.¹¹ At other times, the nevus takes the form of a linear or zosteriform lesion, or just a slightly scaly area of discoloration.^{6,12,13} The acanthosis nigricans form of epidermal nevus, which may be zosteriform or oriented along Blaschko's lines, appears to be a mosaic form of acanthosis nigricans.¹⁴ Various terms have been applied, not always in a consistent manner, to the different clinical patterns.¹³ The term 'nevus verrucosus' (verrucous epidermal nevus) has been used for localized wart-like variants,¹⁵⁻¹⁷ and 'nevus unius lateris' has been used for long, linear, usually unilateral lesions on the extremities.¹⁸ 'Ichthyosis hystrix' refers to large, often disfiguring nevi with a bilateral distribution on the trunk.^{19,20} Mosaicism for chromosome 6 has been found in skin fibroblasts from

skin attached to an epidermal nevus.²¹ Much more common are mutations in fibroblast growth factor receptor 3 (*FGFR3*), an abnormality found also in acanthosis nigricans and some seborrheic keratoses.²²

A recent report describes a patient with a postzygotic mosaic *HRAS* mutation, systematized epidermal nevus, and multiple urothelial cell carcinomas; the mutation was found in the epidermal nevus, three urothelial cell carcinomas, and a lung metastasis.²³ Various tumors have been reported arising in epidermal nevi, as a rare complication. These include basal cell^{24,25} and squamous cell carcinomas,²⁶⁻²⁸ as well as a keratoacanthoma.²⁹ Acne developed at puberty in one epidermal nevus.³⁰ Verrucous epidermal nevus (nevus verrucosus) has been reported in association with an organoid nevus (nevus sebaceus).³¹ Colocalization with psoriasis has also been reported.³²

The term '*epidermal nevus syndrome*' (OMIM 163200) refers to the association of epidermal nevi with neurological, ocular, and skeletal abnormalities, such as epilepsy, learning disability, hypophosphatemic vitamin D-resistant rickets,³³ cardiac arrhythmia,³⁴ cataracts, kyphoscoliosis, and limb hypertrophy; there may also be cutaneous hemangiomas.^{2,7,35-46} Whereas in the past these syndromes had been regarded as variations of a single entity, this is no longer tenable because of differences in the type of epidermal nevus (e.g., organoid vs. keratinocytic) and heritability issues, as indicated in an extensive review of the subject by Happle.^{47,48} The well-defined syndromes are Schimmelpenning syndrome (Chapter 33, p. 951), phakomatosis pigmentokeratolica (Chapter 32, p. 863; Chapter 33, p. 951), nevus comedonicus syndrome (see later), angora hair nevus syndrome, Becker's nevus syndrome (OMIM 604919), Proteus syndrome (see later), type II segmental Cowden's disease, fibroblast growth factor receptor 3 epidermal nevus syndrome, and the CHILD syndrome (see p. 292).^{9,47-51}

Features of Schimmelpenning syndrome, angora hair nevus syndrome, Becker's nevus syndrome, Proteus syndrome, type II segmental Cowden's disease, and fibroblast growth factor receptor 3 epidermal nevus syndrome are briefly discussed here.

The Schimmelpenning syndrome consists of a craniofacial nevus sebaceus (which may display minimal or no sebaceous hyperplasia when involving areas outside the head and neck region), classically combined with craniofacial hemihypertrophy, hemimegalencephaly, and pachygyria-polymicrogyria, accompanied by seizures, mental retardation, and ocular lesions such as coloboma and epibulbar lipodermoid.⁵² A subset of this syndrome features vitamin D-resistant hypophosphatemic rickets.⁴⁷ It is usually sporadic, but paradominant inheritance has been proposed in cases in which several family members are involved.

The angora hair nevus syndrome (Schauder's syndrome) is a non-heritable syndrome that consists of band-like arrangements of white hair arising from dilated follicular pores. Association with a variety of neurological (microcephaly, mental retardation, and seizures), mesodermal, and ocular defects has been reported,⁴⁷ although in a recent case the findings included slight macrocephaly, body asymmetry, a sacral pit, and koilonychia.⁵³ A biopsy from an area of linear hypertrichosis showed an absence of melanin from hair shafts but a normally melanized epidermis, dilated follicular orifices, and mild perifollicular lymphocytic inflammation;⁵³ trichoscopy of another case showed fine, lightly colored hair shafts lacking medullae.⁵⁴

In Becker's nevus syndrome, which usually occurs sporadically but can demonstrate paradominant inheritance, there is an association of Becker's nevus (Chapter 10, p. 337) with ipsilateral hypoplasia of the breast, supernumerary nipples, accessory scrotum, hypoplasia of the labium minus, and a variety of musculoskeletal defects.⁴⁷

Proteus syndrome (OMIM 176920) also occurs sporadically. Findings include a soft, velvety keratinocyte nevus with disproportionate overgrowth of bones and soft tissues, resulting in marked limb asymmetry, asymmetrical macrodactyly, and a characteristic cerebriform hyperplasia of palmo-plantar connective tissues.⁵⁵ The epidermal nevus apparently lacks hyperplasia of adnexal structures,⁴⁷ although a paper

describing the histopathologic features of lesions in proteus syndrome describes these epidermal lesions in several instances as ‘sebaceous nevus’ without detailed descriptions or microscopic images.⁵⁶ The inverse form of Proteus syndrome, the so-called ‘elattoproteus syndrome’ (*elatto* is Greek for ‘minus’), apparently lacks an epidermal nevus.⁵⁷

Type II segmental Cowden’s disease is believed to result from a PTEN germline mutation; in a heterozygous embryo, loss of heterozygosity results in the absence of the wild-type allele and segmental disease, manifested in part by a linear, soft, papillomatous keratinocytic epidermal nevus, as well as vascular nevi and malformations, lipomas, jejunal or colonic polyps, and focal segmental glomerulosclerosis.⁵⁸

The fibroblast growth factor receptor 3 epidermal nevus syndrome (Garcia-Haffner-Happle syndrome) is caused by a mosaic R248C mutation of the *FGFR3* gene. A soft, velvety epidermal nevus of keratinocytic type is combined with cortical atrophy, seizures, and mental retardation.⁵⁹

In addition, there are several less well-defined epidermal nevus syndromes that await organization into specific entities. It remains to be determined whether histopathologic features might play a role in the definition/recognition of these syndromes; they are not further discussed, but they are listed here for completeness:⁴⁸

- Nevus trichilemmocysticus syndrome
- Didymosis aplasticosebacea
- SCALP syndrome (sebaceous nevus, CNS malformations, aplasia cutis congenita, limbal dermoid, pigmented nevus)
- Gobello syndrome
- Bafverstedt syndrome
- NEVADA syndrome (nevus epidermicus verrucosus with angiodysplasia and aneurysms)
- CLOVE syndrome (congenital lipomatous overgrowth, vascular malformations, and epidermal nevus).

Unusual combinations of findings in association with epidermal nevi continue to be reported, including a recent case featuring a woolly hair nevus, ipsilateral epidermal nevus, and a white sponge nevus of the tongue,⁶⁰ and another case combining epidermal nevus syndrome and cutaneous mastocytosis.⁶¹ Systemic cancers of various types may arise at a young age in those with epidermal nevus syndrome.^{62,63} The epidermal nevi, which are often particularly extensive in patients with the syndrome, may be of any histological type.^{64–66} Epidermal nevi have also been reported in association with polyostotic fibrous dysplasia.^{67,68}

Topical treatments such as retinoic acid or 5-fluorouracil have been used to remove the keratotic surface of epidermal nevi and improve the cosmetic appearance. Cryotherapy is often followed by recurrence. Small lesions can be removed by surgical excision. Laser therapy can be used for larger lesions. Scarring may follow the use of the CO₂ laser, but the pulsed erbium:YAG laser seems to give excellent cosmetic results.⁶⁹

Histopathology

At least 10 different histological patterns have been found in epidermal nevi (Figs. 31.1 and 31.2).^{6,13} More than one such pattern may be present in a given example. In more than 60% of cases, the pattern is that of hyperkeratosis, with papillomatosis of relatively flat and broad type, together with acanthosis. There is thickening of the granular layer and often a slight increase in basal melanin pigment. This is the so-called ‘common type’ of epidermal nevus.

Less frequently, the histological pattern resembles acrokeratosis verruciformis, epidermolytic hyperkeratosis (OMIM 600648), or seborrheic keratosis.^{6,13} Epidermal nevi with a seborrheic keratosis-like pattern often have thin, elongated rete ridges with ‘flat bottoms’ – a feature not usually seen in seborrheic keratoses. Rare patterns include

Figure 31.1 Epidermal nevus. There is papillomatosis and acanthosis with overlying laminated hyperkeratosis. (H&E)

Figure 31.2 Epidermal nevus. This variant resembles acanthosis nigricans. (H&E)

the verrucoid, porokeratotic, focal acantholytic dyskeratotic,^{70–74} acanthosis nigricans-like,^{13,75} Hailey–Hailey disease-like,⁷⁶ and incontinentia pigmenti-like (verrucous phase) variants.⁷⁷ A subtype of nevus with acanthosis nigricans-like microscopic features develops during childhood or at puberty; it has been called nevoid acanthosis nigricans or RAVEN (rounded and velvety epidermal nevus).⁷⁸ A lichenoid inflammatory infiltrate has also been reported in an epidermal nevus, although usually the dermis is devoid of inflammatory cells.⁷⁹ Inflammatory linear verrucous epidermal nevus and nevus comedonicus are regarded as distinct entities, although they are sometimes included as histological patterns of epidermal nevus.

A recently described form of epidermal nevus features mild ortho-hyperkeratosis, with only slight papillomatosis, broad acanthosis, and a distinctly palisaded basal layer with a widened space separating this layer from the overlying spinous layer keratinocytes – a configuration known as the ‘skyline’ basal cell layer.^{80–83} These lesions present as flat, hyperkeratotic papules, visible at birth or soon thereafter. One recent paper described them as forming a mosaic configuration in a Blaschko linear distribution.⁸² Lesions of papular epidermal nevus with ‘skyline’ basal cell layer (PENS) have also been associated with mesodermal and neurological defects, suggesting that they may be part of a neuro-cutaneous syndrome in some instances.⁸³

The epidermis overlying an organoid nevus (see p. 951) frequently will show the histological picture of an epidermal nevus. In such cases, this is usually of the common type.

Differential diagnosis

Considerations in the differential diagnosis include verrucae, seborrheic keratoses, and other papillomatous lesions such as acanthosis

nigricans and confluent and reticulated papillomatosis of Gougerot and Carteaud. Old verrucae may lack the typical viropathic changes or the 'in-bowing' of epithelial margins seen in verrucae, and the papillomatosis seen in these lesions can closely mimic that of epidermal nevi. Changes of epidermolytic hyperkeratosis can mimic, to a degree, the viropathic changes of human papillomavirus (HPV) infection. However, in such cases, the absence of characteristic koilocytic cells with 'raisinoid' nuclei and possible extension of vacuolated changes deep within the epidermis favor epidermal nevus. The close-set basaloid cells and pseudohorn cysts of seborrheic keratosis are usually diagnostic, but hyperkeratotic varieties with marked papillomatosis and lacking horn cysts can certainly resemble epidermal nevi. Occasionally, epidermal nevi can have a 'nested' microscopic configuration, exactly mimicking the histopathologic image of a 'clonal' seborrheic keratosis. The nests of cells also create the appearance of globules on dermoscopy – features also associated with both clonal seborrheic keratoses and melanocytic tumors.⁸⁴ Recognition of epidermal nevus then depends on clinical features: an elongated rather than a rounded to oval lesional contour (arguing against seborrheic keratosis) and en bloc movement on the 'wobble test' (characteristic of an epidermal growth).⁸⁴ The diagnosis of seborrheic keratosis should not be made in children and only with caution in young adults; most lesions in these age groups probably represent either epidermal nevi or verrucae. Acanthosis nigricans as well as confluent and reticulated papillomatosis usually have lesser degrees of hyperkeratosis and papillomatosis than ordinarily encountered in epidermal nevi, although the microscopic features of RAVEN are essentially identical to those of acanthosis nigricans. In any event, the clinical features should help exclude these diagnoses in most instances. Nevroid hyperkeratosis of the nipple can mimic one of the distribution patterns of acanthosis nigricans; greater degrees of epidermal change and lack of involvement in other locations tend to exclude acanthosis nigricans in such cases.

INFLAMMATORY LINEAR VERRUCOUS EPIDERMAL NEVUS

Also known by the acronym of ILVEN, inflammatory linear verrucous epidermal nevus is a specific clinicopathological subgroup of epidermal nevi that most often presents as a pruritic linear eruption on the lower extremities.^{2,85–89} Involvement of the genital/perineal region has been reported.⁹⁰ The lesions are usually arranged along the lines of Blaschko.⁹¹ The condition is of early onset, usually in the first 6 months of life.⁹² Familial occurrence is rare.⁹³ Asymptomatic variants and widespread bilateral distribution have been reported,^{94,95} most cases are unilateral. ILVEN has been described in association with the epidermal nevus syndrome (discussed previously)⁹⁶ and in a burn scar.⁹⁷ Squamous cell carcinoma has been reported to develop in ILVEN.⁹⁸

The lesions resemble linear psoriasis both clinically and histologically; in this context, it must be noted that the existence of a linear form of psoriasis has been questioned.^{99,100} Interestingly, the epidermal fibrous protein isolated from the scale in ILVEN is different from that found in psoriasis.^{101,102} Because of the similarities between these two conditions, etanercept has been used to treat widespread ILVEN.¹⁰³

The most widely used treatment is intralesional or potent topical corticosteroids. Both provide temporary relief at best.⁹² Topical calcipotriol may be of some benefit, but it should be used with caution in children.⁹² Destructive therapies have also been disappointing. Small lesions can be surgically removed.

Histopathology

There is psoriasiform epidermal hyperplasia with overlying areas of parakeratosis, alternating with orthokeratosis. Beneath the orthokeratotic areas of hyperkeratosis, there is hypergranulosis, often with a

Figure 31.3 Inflammatory linear verrucous epidermal nevus. There is alternating parakeratosis and orthokeratosis. The parakeratosis overlies a zone of agranulosis, whereas beneath the area of orthokeratosis there is a zone of hypergranulosis with a depressed, cup-like appearance. (H&E)

depressed cup-like appearance; the parakeratosis overlies areas of agranulosis of the upper epidermis (Fig. 31.3).¹⁰⁴ The zones of parakeratosis are usually much broader than in psoriasis. Focal mild spongiosis with some exocytosis and even vesiculation may be seen in some lesions.¹⁰⁵ There is also a mild perivascular lymphocytic infiltrate in the upper dermis. A dense lichenoid infiltrate was present in one case, perhaps representing the attempted immunological regression of the lesion.¹⁰⁶

A case reported as ILVEN of the penis and scrotum, and associated with ipsilateral undescended testicle, is probably a variant of epidermal nevus with epidermolytic hyperkeratosis, based on the published photomicrographs.¹⁰⁷

The immunohistochemical features of ILVEN differ from those found in epidermal nevi.¹⁰⁸ This may simply be a reflection of the inflammatory component of ILVEN.

Differential diagnosis

ILVEN can resemble psoriasis microscopically as well as clinically. However, the presence of alternating orthokeratosis and parakeratosis is not typical of psoriasis, and the pattern of involucrin expression differs as well, because in psoriasis, most suprabasilar keratinocytes are positive for involucrin,^{109,110} whereas in ILVEN the protein is expressed preferentially in orthokeratotic regions.¹¹¹

NEVUS COMEDONICUS

Nevus comedonicus (comedo nevus) is a rare abnormality of the infundibulum of the hair follicle in which grouped or linear comedonal papules develop at any time from birth to middle age.^{112–114} Approximately 50% of cases are evident at birth.¹¹⁵ They are usually restricted to one side of the body, particularly the face, trunk, and neck.^{116–118} Rare clinical presentations have included penile,¹¹⁹ scalp,¹²⁰ palmar,^{121–123} bilateral,¹²⁴ and verrucous lesions.¹²¹ Extensive lesions are an uncommon manifestation.^{125,126} Rarely, abnormalities of other systems, such as the skeletal and neurological systems, are present, indicating that a nevus comedonicus syndrome, akin to the epidermal nevus syndrome, occurs.^{92,127–133} It is regarded as a subset of the epidermal nevus syndrome. Accessory breast tissue was present in one patient.¹³⁴ Clinical association of nevus comedonicus with linear morphea and lichen striatus has been reported; microscopic findings were not provided.¹³⁵ Nevus comedonicus has been reported in association with

hidradenoma papilliferum and syringocystadenoma papilliferum.¹³⁶ All lesions were in the female genital area.¹³⁶ Keratoacanthoma has arisen in a nevus comedonicus.¹³⁷ Inflammation of the lesions is an important complication, resulting in scarring.^{124,138–140}

Topical ammonium lactate, urea, and retinoids have all been tried at some time to treat nevus comedonicus.¹³¹ Antibiotics are required for infected lesions. Small lesions can be excised. For large lesions, the treatment of choice remains to be determined.¹³¹ The erbium:YAG laser is a possibility for these larger lesions.¹⁴¹

Histopathology

There are dilated keratin-filled invaginations of the epidermis. An atrophic sebaceous or pilar structure sometimes opens into the lower pole of the invagination.¹⁴² A small lanugo hair is occasionally present in the keratinous material. Filaggrin expression is increased in the closed comedones seen in this condition.¹⁴³ Inflammation and subsequent dermal scarring are a feature in some cases. A trichilemmal cyst has also been reported arising in a comedo nevus.¹⁴⁴

The epithelial invagination in some cases of palmar involvement has opened into a recognizable eccrine duct.^{122,145} Cornoid lamellae have also been present.^{146–148} It has been suggested that these are cases of eccrine hamartomas, akin to nevus comedonicus and unrelated to porokeratosis.¹⁴⁹

Rare histological patterns associated with comedo nevus-like lesions have included a basal cell nevus,¹⁵⁰ a linear variant with underlying tumors of sweat gland origin,¹⁵¹ and a variant with epidermolytic hyperkeratosis in the wall of the invaginations.¹⁵² One case presented with giant epidermal cysts, some with rupture and foreign body giant cell reaction.^{153,154} Epithelial proliferation, resembling that seen in the dilated pore of Winer, has been noted (Fig. 31.4).¹⁵⁵ A form with dyskeratosis, accompanied often by acantholysis in the wall, is regarded as a distinct entity – familial dyskeratotic comedones (see below).

Dermoscopy of nevus comedonicus has shown homogeneous, circular and barrel-shaped areas of light or dark brown color containing keratin plugs.¹⁵⁶

Electron microscopy

With scanning electron microscopy, two types of keratotic plugs are identified: chrysanthemum-like structures exposed to the skin surface

and cylindrical structures plugging dilated follicular orifices. Transmission electron microscopy has shown poorly differentiated smooth muscle cells adjacent to dilated follicular epithelia, presumably representing primitive arrector pili muscle.¹⁵⁷

FAMILIAL DYSKERATOTIC COMEDONES

Familial dyskeratotic comedones is a rare autosomal dominant condition in which multiple comedones develop in childhood or adolescence, sometimes in association with acne.^{158–161} Sites of involvement include the trunk and extremities and, uncommonly, the palms and soles, the scrotum, and the penis.^{158,162} This entity appears to be distinct from nevus comedonicus and also from the rare condition of familial comedones.^{163,164}

Histopathology

A follicle-like invagination in the epidermis is filled with laminated keratinous material. Dyskeratotic cells are present in the wall of the invagination, particularly in the base. This is associated with acantholysis, which may, however, be mild or inapparent.¹⁵⁹

PSEUDOEPITHELIOMATOUS HYPERPLASIA

Pseudoepitheliomatous (pseudocarcinomatous) hyperplasia is a histopathological reaction pattern rather than a disease sui generis.^{165–167} It is characterized by irregular hyperplasia of the epidermis that also involves follicular infundibula and acrosyringia.^{165,168} This proliferation occurs in response to a wide range of stimuli comprising chronic irritation, including around urostomy and colostomy sites;¹⁶⁹ trauma; the use of permanent makeup;¹⁷⁰ a tattoo site;¹⁷¹ cryotherapy; chronic lymphedema; and various dermal inflammatory processes, such as chromomycosis, sporotrichosis, aspergillosis, pyoderma, bacillary angiomatosis, and actinomycosis.^{166,167,172,173} The lesions occurring around urostomy and colostomy sites take the form of pseudoverrucous papules and nodules.¹⁷⁴ Epidermodysplasia verruciformis (EV)-related human papillomaviruses have been reported in these lesions but specifically excluded in other cases.¹⁷⁵ Pseudoepitheliomatous hyperplasia has been reported in the chronic verrucous lesions that develop in immunocompromised patients who develop herpes zoster/varicella infection (see p. 729). It may also develop in the halogenoderma and in association with chondrodermatitis nodularis helices,¹⁷⁶ Spitz nevi, malignant melanomas, overlying granular cell tumors, cutaneous T-cell lymphomas,¹⁷⁷ and CD30⁺ lymphoproliferative disorders.¹⁷⁸ The term 'pseudorecidivism' has been used for the pseudoepitheliomatous hyperplasia that sometimes develops a few weeks after treatment, by various methods,¹⁷⁹ of a cutaneous tumor.

Histopathology

On microscopic examination, there are prominent, somewhat bulbous, acanthotic downgrowths that in many instances represent expanded follicular infundibula.¹⁶⁵ Ackerman stresses that these structures are epidermal in origin and not follicular.¹⁸⁰ The hyperplasia is not as regular as that seen in psoriasiform hyperplasia. The cells have abundant cytoplasm, which is sometimes pale staining. Unlike squamous cell carcinoma, there are few mitoses and only minimal cytological atypia. Aneuploidy is present in a small number of cases.¹⁸¹ Where the process overlies dermal inflammation, transepidermal elimination of the inflammatory debris may occur, resulting in intraepidermal microabscesses.

In addition to those conditions already mentioned, pseudoepitheliomatous hyperplasia occurs in granuloma fissuratum and prurigo nodularis: these conditions are discussed later.

Figure 31.4 Nevus comedonicus. Keratin-filled invaginations are seen in cross-sectional profile in this example. There are epithelial proliferations resembling that of dilated pore of Winer. (H&E)

Differential diagnosis

The presence of unexplained pseudoepitheliomatous hyperplasia should prompt a search for infectious diseases or associated tumors, such as granular cell tumor, lymphomas (e.g., CD30⁺ lymphoproliferative disorders, extranodal NK/T-cell lymphoma, nasal type),¹⁸² or melanoma.¹⁸³ True squamous cell carcinoma accompanied by pseudoepitheliomatous change can easily be missed, especially in a superficial shave biopsy; careful search may reveal narrow cords of atypical keratinocytes, sometimes arising at the angle of intersection of proliferative epidermis and acanthotic follicular epithelium, suggesting the possibility that a squamous cell carcinoma has arisen from an actinic keratosis. Verrucous carcinoma can be particularly difficult to distinguish from pseudoepitheliomatous hyperplasia, but the former can be suspected when the lesion is exophytic as well as endophytic; contains deeply extending crypts filled with neutrophils and keratinous debris; and shows bulbous, 'pushing' deep margins. Staining for Langerhans cell markers such as CD1a, epidermal growth factor, epidermal growth factor receptor (EGFR)- α , silver nucleolar organizer regions (AgNOR), or proliferating cell nuclear antigen (PCNA) have not been reliable for distinguishing cutaneous pseudoepitheliomatous hyperplasia from squamous cell carcinoma.^{183,184} p53 staining is positive in both lesions, but it tends to be weaker in cutaneous pseudoepitheliomatous hyperplasia and mainly concentrated in the basal cell layer.¹⁸⁵ p53 staining may be more useful in mucosal specimens because pseudoepitheliomatous hyperplasia shows only basilar reactivity, whereas squamous cell carcinoma shows full-thickness intraepithelial nuclear reactivity.¹⁸⁶ Significantly increased matrix metalloproteinase 1 (MMP-1) staining within tumor cells and adjacent stroma was seen in mucosal squamous cell carcinoma, in contrast to pseudoepitheliomatous hyperplasia, in which MMP-1 staining was largely confined to basal and parabasal cells, without stromal staining; the specificity and sensitivity of MMP-1 for squamous cell carcinoma were 94 and 81%, respectively.^{184,186} Expression of various MMPs may be helpful in distinguishing pseudoepitheliomatous hyperplasia from squamous cell carcinoma in chronic wounds, such as leg ulcers. For example, MMP-7 is expressed in squamous cell carcinomas but is absent from pseudoepitheliomatous hyperplasia arising in this setting.^{183,187} In another recent study of head and neck lesions, reduced expression of E-cadherin and expression of contactin were features of squamous cell carcinoma and not pseudoepitheliomatous hyperplasia.¹⁸⁸ A multiplex TaqMan polymerase chain reaction (PCR) assay was helpful in distinguishing the two conditions in 54 of 58 cases; in squamous cell carcinomas, the gene *C15orf48* had higher expression than *KRT9*, whereas the reverse was the case in pseudoepitheliomatous hyperplasia.¹⁸⁹

GRANULOMA FISSURATUM

Granuloma fissuratum¹⁹⁰ (acanthoma fissuratum,¹⁹¹ spectacle-frame acanthoma¹⁹²) is a firm, flesh-colored or pink nodule with a grooved central depression that develops at the site of focal pressure and friction from poorly fitting prostheses such as spectacles.^{191,193} Accordingly, such lesions are found on the lateral aspect of the bridge of the nose near the inner canthus,¹⁹⁴ in the retroauricular region,¹⁹⁰ and, rarely, on the cheeks. A similar lesion develops in the mouth as a result of poorly fitting dentures. Lesions have also been reported in the male and female genitalia.^{195,196}

The lesions are painful or tender, and they may ulcerate. Clinically, they resemble basal cell carcinomas, although the central groove – typically corresponding to the point of contact with the spectacle frame – usually allows a correct diagnosis to be made.¹⁹⁷ Lesions heal within weeks of correction of the ill-fitting prosthesis.

Figure 31.5 Granuloma fissuratum. There is focal pseudoepitheliomatous hyperplasia. (H&E)

Histopathology

The lesion is characterized by marked acanthosis of the epidermis with broad and elongated rete pegs (Fig. 31.5). There is a central depression, corresponding with the groove noted macroscopically, and here the epidermis is attenuated and sometimes ulcerated.^{190,192} There is mild hyperkeratosis and often a prominent granular layer overlying the acanthotic epidermis; there may be parakeratosis and mild spongiosis in the region of the groove or adjacent to it.

The dermis shows telangiectasia of the small blood vessels with an accompanying chronic inflammatory cell infiltrate, which is usually mild and patchy. The infiltrate includes plasma cells, lymphocytes, and some histiocytes. There is focal fibroblastic activity and focal dermal fibrosis, with mild hyalinization of collagen beneath the groove. There may be mild edema of the superficial dermis.

PRURIGO NODULARIS

Prurigo nodularis is an uncommon disorder in which there are usually numerous persistent, intensely pruritic nodules. There is a female predominance. In a series of 72 cases, the ages ranged from 15 to 92 years, with a median age at presentation of 55 years.¹⁹⁸ They involve predominantly the extensor aspects of the limbs, often symmetrically, but they may also develop on the trunk, face, scalp, and neck.^{199–202}

The nodules are firm, pink, and sometimes verrucous or focally excoriated. They are approximately 5–12 mm in diameter and range from few in number to more than 100.¹⁹⁹ Solitary lesions also occur. The intervening skin may be normal or xerotic; sometimes there is a lichenified eczema.¹⁹⁹ There may be an underlying cause for the pruritus, such as a metabolic disorder,¹⁹⁸ bites, folliculitis, the pruritic eruption of HIV infection,^{203,204} or atopic state.^{199,205} It has arisen in a healed herpes zoster scar – an isotopic response.²⁰⁶ Prurigo nodularis-like lesions have occurred in association with bullous pemphigoid (pemphigoid nodularis),²⁰⁷ linear IgA bullous disease,²⁰⁸ and IgG4-related disease.²⁰⁹ Mycobacteria have been cultured from, or demonstrated in, tissue sections in nearly one-fourth of cases in one study.²¹⁰ The significance of this finding is uncertain; it has not been confirmed. The tretinoin derivative etretinate, used in the treatment of a range of skin conditions, has been incriminated in several cases.²¹¹ Stress is sometimes a factor, although psychological factors may have been overstated in the past.²¹² Prurigo nodularis is regarded by some authors as an exaggerated form of lichen simplex chronicus (see p. 96). Substance P-immunoreactive nerves and calcitonin gene-related peptide are markedly increased in lesions of prurigo nodularis.²¹³

Capsaicin, an alkaloid that interferes with the perception of pruritus and pain by depletion of neuropeptides in small sensory nerves in the skin, has been used successfully in the treatment of prurigo nodularis.²¹⁴ Thalidomide has also been used, but care should be taken to exclude an underlying peripheral neuropathy before commencing this drug.^{215–217} Topical and intralesional steroids, emollients, topical antipruritics, doxepin, and cryotherapy are other treatments that have been used.^{198,213}

Histopathology^{199,218}

There is prominent hyperkeratosis, often focal parakeratosis, and marked irregular acanthosis that often is of pseudoepitheliomatous proportions (Fig. 31.6). Sometimes the hyperplasia is more regular and vaguely psoriasiform in type. There may be pinpoint ulceration from excoriation. Mitoses are usually increased among the keratinocytes. A hair follicle is often present in the center of each acanthotic downgrowth (Fig. 31.7).²¹⁹

The upper dermis shows an increase in small blood vessels, and there is often an increase in the numbers of dermal fibroblasts, some of which may be stellate. There are usually fine collagen bundles in a vertical orientation in the papillary dermis. The arrectores pilorum

Figure 31.6 Prurigo nodularis. There is marked pseudoepitheliomatous hyperplasia. (H&E)

Figure 31.7 Prurigo nodularis. There is focal excoriation and bulbous rete pegs. (H&E)

muscles may be prominent. A syringomatous proliferation of eccrine sweat ducts is a rare finding.²²⁰ The inflammatory cell infiltrate in the dermis is usually only mild and includes lymphocytes, mast cells, histiocytes, and sometimes eosinophils. Extracellular deposition of eosinophil granule protein is usually present.²²¹ Epidermal mast cells and Merkel cells may be seen.^{218,222} The mast cells are increased in size and become more dendritic.²²³ They are seen in close vicinity to nerves that functionally express increased amounts of nerve growth factor receptor.²²³

Hypertrophy and proliferation of dermal nerve fibers has been emphasized by most,^{224–227} but it was not a prominent feature in two large series of cases.^{218,228} However, using immunofluorescence methods, a predominance of substance P-positive sensory nerve fibers over tyrosine hydroxylase-positive sympathetic nerve fibers was found in prurigo nodularis as well as chronic pruritus lesions.²²⁹ Small neuroid nodules with numerous Schwann cells have been reported in the dermis.^{230,231} Immunohistochemistry has revealed that calcitonin gene-related peptide (CGRP) is expressed in increased amounts in nerve fibers in prurigo nodularis; this may be of significance in the recruitment of eosinophils and mast cells into lesional tissue.²³² The CD10 preparation shows an onion skin-like cuff of positively staining dermal cells surrounding the hyperplastic downgrowths of epidermis.²³³

Electron microscopy

There is an increase in cutaneous nerves in some cases²³⁰ and vacuolization of the cytoplasm of Schwann cells.^{218,234} Myelinated nerves may show various degrees of demyelination.²³⁴

Differential diagnosis

In addition to well-differentiated squamous cell carcinoma, prurigo nodularis should be distinguished from keratoacanthoma, but the latter lesion has a well-developed keratin-filled crater with a buttressing arrangement of the adjacent epidermis, glassy-appearing cytoplasm, and often intraepidermal neutrophilic abscesses. Pemphigoid nodularis and the rare variant of linear IgA disease presenting as prurigo nodularis are best recognized by performing direct immunofluorescence studies, but occasionally hematoxylin and eosin (H&E)-stained sections may show evidence of subepidermal separation with accumulations of eosinophils or neutrophils, providing a clue to one of these diagnoses.²⁰⁷ Other forms of pseudoepitheliomatous hyperplasia that can resemble prurigo nodularis include halogen eruptions (bromoderma and iododerma), although these often show pronounced dermal edema and a neutrophilic infiltrate that may be folliculocentric, or the group of chronic cutaneous infections that produce a blastomycosis-like tissue reaction pattern.

ACANTHOMAS

Acanthomas are benign tumors of epidermal keratinocytes.²³⁵ The proliferating cells may show normal epidermoid keratinization or a wide range of aberrant keratinization, including epidermolytic hyperkeratosis (epidermolytic acanthoma), dyskeratosis with acantholysis (warty dyskeratoma), or acantholysis alone (acantholytic acanthoma).²³⁵ These abnormal forms of keratinization occur in a much broader context and were discussed in Chapter 9 (pp. 301–304). Brief mention of these forms of acanthoma is made again for completeness. Keratoacanthomas (see p. 828) are not usually considered in this category, although there is no logical reason for their exclusion. The following acanthomas are discussed here:

- Epidermolytic acanthoma
- Warty dyskeratoma
- Acantholytic acanthoma
- Seborrheic keratosis

- Dermatosi papulosa nigra
- Melanoacanthoma
- Clear cell acanthoma
- Clear cell papulosis
- Large cell acanthoma.

EPIDERMOLYTIC ACANTHOMA

Epidermolytic acanthoma is an uncommon lesion that may be solitary, resembling a wart, or multiple. It shows the histopathological changes of epidermolytic hyperkeratosis and is therefore considered in Chapter 9 with other lesions showing this disorder of epidermal maturation and keratinization (see p. 302).

WARTY DYSKERATOMA

Warty dyskeratomas are rare, usually solitary, papulonodular lesions with a predilection for the head and neck of middle-aged and elderly individuals (see p. 310). They show suprabasilar clefting, with numerous acantholytic and dyskeratotic cells within the cleft and an overlying keratinous plug.

ACANTHOLYTIC ACANTHOMA

Acantholytic acanthoma is a solitary tumor with a predilection for the trunk of older individuals.^{236,237} It usually presents as an asymptomatic keratotic papule or nodule. Uncommonly, it may resemble a molluscum contagiosum clinically.²³⁸ Multiple lesions have been reported in a renal transplant recipient.²³⁹

Histopathology²³⁶

The features include variable hyperkeratosis, papillomatosis, and acanthosis, together with prominent acantholysis, most often involving multiple levels of the epidermis (Fig. 31.8). There is sometimes suprabasilar or subcorneal cleft formation, but there is no dyskeratosis. The pattern resembles that seen in pemphigus or Hailey–Hailey disease, but there has been no evidence of these diseases in the cases reported.

SEBORRHEIC KERATOSIS

Seborrheic keratoses (senile warts, basal cell papillomas) are common, often multiple, benign tumors that usually first appear in middle life.^{240,241} They may occur on any part of the body except the palms and soles, although there is a predilection for the chest, interscapular region, waistline, and forehead. Seborrheic keratoses are sharply demarcated gray-brown to black lesions, which are slightly raised. They may be covered with greasy scales. Most lesions are no more than approximately 1 cm in diameter, but larger variants, sometimes even pedunculated, have been reported.^{242–244} A flat plaque-like form is sometimes found on the buttocks or thighs. This should not be confused with the lightly pigmented plaques of unwashed skin that have variously been called keratoderma simplex,²⁴⁵ dermatitis artefacta, and ‘terra firma-forme’ dermatosis (see p. 343). Rarely, it arises in a nevus sebaceus.²⁴⁶

Rare clinical variants include a familial form, which may be of early or late onset,^{247–249} and a halo variant with a depigmented halo around each lesion.²⁵⁰ The Meyerson phenomenon (eczematous halo) may rarely involve a seborrheic keratosis.²⁵¹ A cockarde (targetoid) seborrheic keratosis has recently been described.²⁵² Multiple seborrheic keratoses may sometimes assume a patterned arrangement along lines of cleavage²⁵³ or a linear (‘raindrop’) pattern.²⁵⁴ A keratin horn is sometimes present, particularly in the elderly.²⁵⁵ The eruptive form

Figure 31.8 (A), (B) Acantholytic acanthoma. Acantholysis involves the lower layers of the hyperplastic epidermis. There is a thick, orthokeratotic stratum corneum. (H&E)

associated with internal cancer (sign of Leser and Trélat) is discussed later. Inflammation has developed in seborrheic keratoses after docetaxel treatment.²⁵⁶

The nature of seborrheic keratoses is still disputed. A follicular origin has been proposed. They have also been regarded as a late-onset nevoid disturbance or the result of a local arrest of maturation of keratinocytes.²⁵⁷ Various histopathologic types of seborrheic keratosis appear to manifest different patterns of keratin and filaggrin expression, suggesting differentiation toward terminal squamous epithelium, undifferentiated basaloid cells, the hair bulge, or follicular infundibulum.²⁵⁸ Of interest is the finding of somatic mutations in *FGFR3* in a subset of patients with adenoid and flat seborrheic keratoses.^{259,260} Increased age appears to be a risk factor for these mutations. Furthermore, their preferential occurrence in seborrheic keratoses of the head and neck suggests a causative role for cumulative lifetime ultraviolet light exposure.²⁶⁰ Mutations in *FGFR3* are also found in epidermal nevi and acanthosis nigricans. Somatic mutations in *PIK3CA* have also been reported.²⁴⁹ Other reported low-incidence mutations in seborrheic keratosis include a somatic *EGFR* p.L858R mutation, *HRAS* mutations p.G13R and p.Q61L, and a previously reported *KRAS* p.G12V mutation.²⁶¹ HPV has been detected in a small number of cases,²⁶² particularly from the genital region.²⁶³ It has also been found in the seborrheic keratoses of patients who have epidermodysplasia verruciformis.^{264,265} The DNA of epidermodysplasia verruciformis-associated human papillomaviruses has been

detected in nongenital seborrheic keratoses.²⁶⁶ Several cases of necrotizing herpesvirus infection complicating a seborrheic keratosis have been reported.²⁶⁷ Endothelin-1, a keratinocyte-derived cytokine with a stimulatory effect on melanocytes, is thought to be involved in the melanization of seborrheic keratoses.^{268,269} The basosquamous cell acanthoma of Lund, the inverted follicular keratosis, and the stucco keratosis have all been regarded, at some time, as variants of seborrheic keratosis.^{235,270}

A case can be made for submitting all suspected seborrheic keratoses for histological examination because clinical misdiagnosis can occur.^{271,272}

Shave excision, curette and cautery, and cryotherapy have all been used to treat seborrheic keratoses. In Australia, excision is sometimes used, but there is no Medicare reimbursement for such excisions. Tazarotene cream 0.1% was found to be cosmetically acceptable in a trial comparing cryosurgery, tazarotene, topical imiquimod, and topical calcipotriene.²⁷³

Histopathology^{235,274}

Seborrheic keratoses are sharply defined tumors that may be endophytic or exophytic.²⁷⁴ They are composed of basaloid cells with a varying admixture of squamoid cells. Keratin-filled invaginations and small cysts (horn cysts) are a characteristic feature. Nests of squamous cells (squamous eddies) may be present, particularly in the irritated type. The squamous eddies of irritated seborrheic keratoses are anatomically related to acrotrichia.²⁷⁵ Approximately one-third of seborrheic keratoses appear hyperpigmented in H&E-stained sections.²⁴³

At least nine distinct histological patterns have been recognized: acanthotic (solid), reticulated (adenoid), hyperkeratotic (papillomatous), clonal, irritated, inflamed, desmoplastic, adamantinoid, and with pseudorosettes.^{274,276,277} Overlapping features are quite common. The *acanthotic* type is composed of broad columns or sheets of basaloid cells with intervening horn cysts. The *reticulated (adenoid)* type has interlacing thin strands of basaloid cells, often pigmented, enclosing small horn cysts (Fig. 31.9). This variant often evolves from a solar lentigo.²⁷⁴ The *hyperkeratotic* type is exophytic, with varying degrees of hyperkeratosis, papillomatosis, and acanthosis (Fig. 31.10). There are both basaloid and squamous cells. *Clonal* seborrheic keratoses (Fig. 31.11) have intraepidermal nests of basaloid cells resembling the Borst-Jadassohn phenomenon (see p. 804).²⁷⁸ In the *irritated* variant, there is a heavy inflammatory cell infiltrate, with lichenoid features, in the upper dermis. Apoptotic cells are present in the base of the lesion and in areas of squamous differentiation.²⁷⁹ This represents the attempted

immunological regression of a seborrheic keratosis.^{280,281} The term *lichenoid* seborrheic keratosis is a preferable term to irritated seborrheic keratosis. Kamino bodies (see p. 851) are rarely found in this type.²⁸² Sometimes there is a heavy inflammatory cell infiltrate without lichenoid qualities;²⁸³ rarely, neutrophils are abundant in the infiltrate.²⁴³ This may be regarded as a true *inflammatory* variant, although often lesions with features overlapping with those of the irritated (lichenoid) type are found.²⁸³ In the *desmoplastic* variant, there are irregular squamous nests and cords of cells extending into a desmoplastic stroma. The trapped cells may mimic a squamous cell carcinoma.²⁷⁶ This variant is analogous to the desmoplastic tricholemmoma. A variant with intercellular mucin and small basaloid keratinocytes with spindled cytoplasm has been called an *adamantinoid* seborrheic keratosis.²⁷⁷ In the variant with *pseudorosettes*, basaloid cells are radially arranged around central, small empty spaces. The lesion is acanthotic with occasional horn cysts.²⁷⁷

Trichilemmal differentiation with glycogen-rich cells is an uncommon, usually focal, change.^{284,285} So too is sebaceous differentiation.²⁸⁶ Acantholysis is another uncommon histological feature.^{287,288} Basal clear cells are sometimes present in seborrheic keratoses, often with upward nuclear displacement. These cells express keratin markers, including high-molecular-weight keratins CK5 and CK14, often at the periphery of the cells (sometimes best appreciated by high-power examination),

Figure 31.10 Seborrheic keratosis of hyperkeratotic type with marked papillomatosis and hyperkeratosis. (H&E)

Figure 31.9 Reticulated (adenoid) seborrheic keratosis. There are irregular, acanthotic downgrowths. (H&E)

Figure 31.11 Clonal seborrheic keratosis. Nests of keratinocytes show the Borst-Jadassohn phenomenon. (H&E)

but not S100 or melan-A. They may mimic melanoma *in situ* on H&E sections.^{289,290} Trichostasis spinulosa with multiple retained hair shafts has also been reported.²⁹¹ Amyloid in the underlying dermis is another incidental finding.²⁷⁴ A verruciform xanthoma-like lesion has also developed in a seborrheic keratosis.²⁹²

The development of a basal cell or squamous cell carcinoma or a keratoacanthoma in a seborrheic keratosis is a rare event.^{293–303} More common is the juxtaposition or ‘collision’ of these lesions,^{304,305} this may have been the case in a recent report of sebaceous carcinoma associated with seborrheic keratosis.³⁰⁶ Another finding is epidermal atypia of varying severity in the cells of a seborrheic keratosis; a progressive transformation to *in situ* squamous cell carcinoma (bowenoid transformation) may occur.^{307–315} Rarely, a malignant melanoma may develop in a seborrheic keratosis.^{300,316,317} In a study of 639 consecutive seborrheic keratoses, an associated (adjacent to or contiguous with) lesion was present in 85 cases (9%).³⁰¹

Dermoscopy is a reliable method of distinguishing these lesions from malignant melanoma and other pigmented lesions. The classic criteria – milium-like cysts and comedo-like openings – have a high prevalence, but other features, such as fissures and ridges, hairpin blood vessels, sharp demarcation, moth-eaten borders, and ‘fat fingers’, may also be present.^{318–320} These findings differ from basal cell carcinoma, in which there are large blue-gray ovoid nests, multiple blue-gray globules, leaf-like areas, spoke wheel areas, arborizing vessels, sometimes ulceration, and lack of a pigment network.³²⁰ Suggestive findings of clonal seborrheic keratosis include the combination of milium-like cysts and blue globules within a sharply demarcated lesion.³²¹ Digital dermoscopy, with analysis of color features, can also be helpful in the differentiation of squamous cell carcinoma *in situ* from seborrheic keratosis; large patches of scale crust, with shades of yellowish to dark orange and tan, characterize squamous cell carcinoma *in situ*, whereas small scales with a white to tan color are more typical of seborrheic keratosis.³²² Scale crust areas are more erythematous (red), which is probably a reflection of the increased papillary dermal vascularity associated with squamous cell carcinoma *in situ*.³²²

Reflectance confocal microscopy shows a honeycomb configuration, within which are densely packed, rounded to polymorphous papillae surrounded by rims of bright, monomorphous cells. There are keratin-filled invaginations and corneal pseudocysts; melanophages and looped vessels in the dermal papillae that appear to be oriented obliquely are also found.^{323,324} Clonal seborrheic keratoses display intraepidermal clusters of pigmented cells, referred to as a ‘clod pattern’, with small, bright dermal papillae that sometimes contain melanophages. This ‘clod pattern’ can also be seen in nevi and melanomas, but on higher magnification the cell clusters are seen to be composed of polygonal keratinocytes with bright cytoplasm, distinguishable from atypical melanocytes.³²¹ Irritated seborrheic keratoses studied by this method show whirlpool-like structures with plump, bright material at their centers (squamous eddies), spongiosis, and dendritic cells in the epidermis.³²⁵

Electron microscopy

Ultrastructural studies have shown that the small basaloid cells are related to cells of the epidermal basal cell layer. Clusters of melanosomes, which are often membrane bound, may be found within the cells.³²⁶ Langerhans cells are probably not increased,³²⁷ as originally reported.³²⁸

Differential diagnosis

The majority of seborrheic keratoses are readily diagnosable, but there are differential diagnostic considerations, some of which are relatively trivial and a few of which are of greater diagnostic import. The lesions of acrokeratosis verruciformis of Hopf can show ‘church-spired’ papillomatosis that is virtually indistinguishable from hyperkeratotic forms of seborrheic keratosis, especially stucco keratosis. Occasionally, foci of acantholysis can be identified in these lesions. In addition, clinical history is important because lesions of acrokeratosis verruciformis begin at birth, during childhood, or at puberty, whereas seborrheic keratoses have a much later time of onset. Flegel’s disease (hyperkeratosis lenticularis perstans) consists of flat, hyperkeratotic papules that

commonly arise on the lower legs and feet. Autosomal dominant transmission has been reported. Microscopically, these again may resemble hyperkeratotic seborrheic keratoses, but compact orthokeratosis, flattening of the underlying epidermis, and acanthosis or papillomatosis at the margins are reasonably characteristic of Flegel’s disease, as is the dense lichenoid infiltrate that is also present in a number of examples. The inverted follicular keratosis (basosquamous acanthoma of Lund) has an architectural resemblance to trichilemmoma, another lobulated, endophytic epithelial tumor that may be arranged about a central follicular structure. However, the latter tumors feature clear cells (due to the presence of glycogen), a distinctly palisaded basilar layer, and a surrounding cuticular basement membrane. Although a distinction between these two lesions per se is not a crucial one, recognition of trichilemmoma may be important because of its association with Cowden’s disease. Many of the seborrheic keratosis variants can resemble verrucae, particularly because the latter do not always possess easily recognizable viral inclusions or other viropathic changes. As noted previously, studies of seborrheic keratoses of the genital region have revealed the presence of HPV in many of these lesions. On the other hand, similar investigations of inverted follicular keratoses have generally been negative for HPV. Seborrheic keratosis-like lesions in children are more likely to be either verrucae or epidermal nevi (discussed previously).

Dermatopathologists frequently encounter hyperkeratotic lesions that are more squamoid than basaloid, lack horn cysts, and have varying degrees of irregular papillomatosis, acanthosis, or scale crust formation. These less than diagnostic lesions are often signed out as seborrheic keratoses, verrucae, or simply as ‘acanthomas’. This would seem to be a reasonable approach in the absence of clinical data to the contrary. Of greater concern are seborrheic keratoses that mimic premalignant or malignant epidermal tumors. Acanthotic seborrheic keratoses composed of close-set basaloid cells can resemble the variant of Bowen’s disease that displays minimal keratinocyte pleomorphism. In such instances, careful evaluation of lesional keratinocytes is crucial: subtle loss of maturation, variability of nuclear size, formation of multinucleate cells, and frequent mitotic figures at all levels of the epidermis would be clues pointing toward Bowen’s disease as the correct diagnosis. As noted previously, seborrheic keratosis with basal cell clear cells can resemble melanoma *in situ* but can be distinguished by the pattern of nuclear displacement and particularly by differential staining with cytokeratins and melanocytic markers.²⁹⁰ The clear cells are cytokeratin 7 negative, which argues against extramammary Paget’s disease, and cytokeratin 14 positive, a feature not expected in pagetoid Bowen’s disease (which is typically CK14 negative).²⁹⁰

Clonal (nested) seborrheic keratoses resemble other lesions typified by the Borst–Jadassohn phenomenon, especially benign or malignant hidroacanthoma or Bowen’s disease with a pagetoid or nested configuration. Hidroacanthomas are basically intraepidermal poromas. The nests are composed of close-set cells with small nuclei that contain glycogen, which is not the case in seborrheic keratoses. Special staining sometimes demonstrates sweat gland differentiation in these tumors. Significant pleomorphism and atypia among nested cells may indicate malignant hidroacanthoma, whereas pagetoid or nested Bowen’s disease often shows foci of intraepidermal atypia in non-nested portions of the lesion. In a study comparing clonal seborrheic keratosis with pagetoid Bowen’s disease, the most helpful morphologic features were mitotic figures, crowding of nuclei, and necrotic keratinocytes – findings favoring Bowen’s disease.³²⁹ Immunohistochemical staining can also be helpful in this regard because nests in clonal seborrheic keratosis are cytokeratin 10 negative and bcl-2 positive.³²⁹

Another concern is the problem of the irritated seborrheic keratosis and its differentiation from hypertrophic actinic keratosis or squamous cell carcinoma. Occasionally, a lesion with scale crusting, squamous eddy formation, and spongiosis also shows degrees of keratinocyte atypia, mostly manifested by nuclear hyperchromasia, variation in

nuclear size, and scattered mitotic figures. In such instances, distinction from squamous cell carcinoma can be problematic. In the editor's experience, this situation arises most often (but not invariably) in elderly individuals. These lesions require particularly close attention to architectural and cytologic details. In contrast to squamous cell carcinoma, irritated seborrheic keratoses show limited pleomorphism, absence of atypical mitoses, and lack of significant atypia in lower epidermal layers and basilar keratinocytes. Most often, the diagnosis can be established with confidence using these guidelines, but there are occasional lesions that defy accurate classification. This often occurs in the case of shaved lesions, where the entire base cannot be visualized. In these instances, and particularly in view of the known instances of seborrheic keratosis associated with premalignant and malignant lesions, it is probably best to identify the lesion as consistent with irritated seborrheic keratosis but with atypical features, and re-excision for assurance of complete removal should be advised.

Leser-Trélat sign

The sign of Leser and Trélat is defined as the sudden increase in the number and size of seborrheic keratoses associated with an internal cancer.³³⁰⁻³³² Approximately 100 such cases have been reported,³³³⁻³³⁶ although some of them are poorly documented as genuine examples of the sign.^{337,338} Other cutaneous paraneoplastic conditions, such as acanthosis nigricans, hypertrichosis lanuginosa, and acquired ichthyosis, are sometimes present as well.³³⁹⁻³⁴² A patient with type 2 diabetes mellitus developed the sign of Leser-Trélat along with acanthosis nigricans, finger pebbles, and numerous acrochordons; no internal malignancy was found.³⁴³ Pruritus is also common.³³³ A gastrointestinal tract adenocarcinoma is the most frequent accompanying cancer,^{344,345} followed by lymphoproliferative disorders.³⁴⁶⁻³⁴⁹ The various cancers reported with this sign are analyzed in several reviews and case reports.^{334,340,341,350} Metastases are frequently present, and most patients have a poor prognosis.^{339,341}

The seborrheic keratoses may precede,³⁵¹ follow, or develop concurrently with the onset of symptoms of the cancer.^{341,352} Cases purporting to represent chemotherapy-induced lesions have been reported.³⁵³ Involution of the seborrheic keratoses has followed treatment of the cancer. The sign has also occurred during the course of the disease.³⁵⁴ The lesions are most frequent on the trunk. A variant in which they were linear in distribution has been reported.³⁵⁵

The mechanism responsible for the appearance of these keratoses is not known. Epidermal growth factor does not appear to be increased,³⁴⁵ although the structurally related transforming growth factor- α was increased in one report.³³⁴ Elevated insulin-like growth factor was present in a patient with eruptive seborrheic keratoses and solitary fibrous tumor of the pleura.³⁵⁶ Inflammation of seborrheic keratoses can be an early manifestation of the sign,³⁵⁷ and it is possible that a host inflammatory response directed toward existing but subtle seborrheic keratoses could account for the rapid increase of lesions in some cases. On the other hand, inflammation of seborrheic keratoses triggered by known factors, such as chemotherapeutic agents, can produce what has been called a 'pseudo sign of Leser-Trélat'.^{358,359}

Eruptive seborrheic keratoses have rarely been reported during the course of an erythrodermic condition.^{360,361} Transient, eruptive seborrheic keratoses have developed in patients with erythrodermic pityriasis rubra pilaris,³⁶² erythrodermic psoriasis, and an erythrodermic drug eruption.³⁶³ They have also been reported in a patient with acromegaly,³⁶⁴ in one with HIV infection,³⁶⁵ and also in a heart transplant recipient.³⁶⁶

Histopathology³⁴¹

Histological examination of the skin lesions has only been made in isolated cases.³⁶⁷ In some reports, typical seborrheic keratoses have been present. In other instances, nonspecific hyperkeratosis and

Figure 31.12 Sign of Leser-Trélat. This is a seborrheic keratosis-like lesion featuring hyperkeratosis, papillomatosis, and acanthosis. Note the lymphocytic inflammation, which was not triggered by chemotherapy in this case. This patient also presented with tripe palms. (H&E)

papillomatosis without acanthosis have been noted.³⁴¹ Florid cutaneous papillomatosis with hyperkeratosis and acanthosis has also been described (Fig. 31.12).³⁶⁸ The regression of lesions following treatment of the underlying cancer appears to be associated with a mononuclear cell infiltrate in the upper dermis and lower epidermis.³⁶¹

DERMATOSIS PAPULOSA NIGRA

Although regarded by some as a variant of seborrheic keratosis,²⁴³ dermatosis papulosa nigra is a clinically distinctive entity, found almost exclusively in black adults, with a female preponderance.³⁶⁹ A familial predisposition is often present.³⁷⁰ There are multiple small pigmented papules, with a predilection for the malar area of the face. The neck and upper part of the trunk may also be involved. Lesions have been found in 10-35% of the black population in the United States.³⁷¹ An eruptive form has been reported in association with an adenocarcinoma of the colon.³⁷²

Electrodesiccation is the treatment of choice, particularly if multiple lesions are present.³⁷⁰

Histopathology³⁷¹

Dermatosis papulosa nigra is characterized by hyperkeratosis, elongated and interconnected rete ridges, and hyperpigmentation of the basal layer (Fig. 31.13). There are often keratin-filled invaginations of the epidermis. The picture is similar to that of the reticulate type of seborrheic keratosis. In contrast to seborrheic keratoses, the epithelial proliferation in dermatosis papulosa nigra is not usually composed of basaloid cells.

MELANOACANTHOMA

The term 'melanoacanthoma' was introduced in 1960 for a rare benign pigmented lesion that is composed of both melanocytes and keratinocytes.³⁷³ The lesion is a slowly growing, usually solitary, tumor of the head and neck, or trunk, of older people.³⁷⁴⁻³⁷⁶ Clinically, a melanoacanthoma resembles a seborrheic keratosis or a melanoma, and it may grow to 3 cm or more in diameter.³⁷⁷ It is best regarded as a variant of seborrheic keratosis. Melanoacanthoma has been recorded

Figure 31.13 Dermatitis papulosa nigra. There are interconnected rete pegs and hyperpigmentation of the basal layer. (H&E)

Figure 31.14 Melanoacanthoma. Heavily pigmented dendritic melanocytes can be seen. Limited pigment transfer to adjacent keratinocytes has occurred. (H&E)

as arising from mucous membranes: such lesions represent an unrelated disorder.^{378–380}

Histopathology^{374,377,381}

There is some resemblance to a seborrheic keratosis, with an acanthotic, slightly verrucous epidermis composed of both basaloid and spinous cells.³⁸¹ The basaloid cells sometimes form islands, whereas the spinous cells form foci with central keratinization and horn pearl formation (endokeratinization). Numerous dendritic melanocytes are scattered throughout the lesion.³⁷⁴ The melanocytes contain mature melanosomes and are heavily pigmented. The neighboring keratinocytes are only sparsely pigmented (Fig. 31.14).³⁸² There is usually pigment in macrophages in the upper dermis. The dendritic melanocytes express S100 protein and HMB-45.³⁸⁰ The epithelium of oral lesions is acanthotic and spongiotic, and it contains numerous benign-appearing pigmented dendritic melanocytes. Variable submucosal inflammation can also be observed,³⁸³ and melanophages are readily identified.³⁸⁴

CLEAR CELL ACANTHOMA

Clear cell acanthoma (pale cell acanthoma) is an uncommon firm brown-red dome-shaped nodule or papule, 5–10 mm or more in diameter, with a predilection for the lower part of the legs of middle-aged and elderly individuals.^{385–389} Giant forms have been described.^{390,391} Rarely, other sites have been involved;^{392–394} onset in younger patients has also been recorded.³⁹⁵ Although usually solitary, multiple tumors have been described, and a few patients with multiple clear cell acanthomas have also had varicose veins and/or ichthyosis.^{396–400} In one case, the lesion developed over a melanocytic nevus.⁴⁰¹ Associated conditions, both adjacent to and underlying a clear cell acanthoma, are common.⁴⁰² The lesions may have a crusted surface and may bleed with minor trauma. A scaly collarette and vascular puncta on the surface of the lesion are common.^{385,403,404} Growth is slow, and the tumor may persist for many years. Spontaneous involution has been reported.⁴⁰⁵

The exact nosological position of this lesion is uncertain, but it has generally been considered to be a benign epidermal neoplasm (as originally proposed by Degos) rather than a reactive hyperplasia of inflammatory origin.^{392,406} It does not show trichilemmal differentiation.⁴⁰² However, the expression of cytokeratins is similar to that seen in some inflammatory dermatoses.⁴⁰⁷ Furthermore, clear cell acanthoma has developed in a psoriatic plaque.⁴⁰⁸ The rare case showing spontaneous regression of disseminated eruptive lesions also suggests the possibility of an inflammatory etiology.⁴⁰⁹

Clear cell acanthomas may be treated with excision, shave excision, cryotherapy, and curettage and electrofulguration.³⁹⁴ Cryotherapy usually requires three or four courses. Because many cases are misdiagnosed clinically as basal cell carcinomas, they are often surgically removed.

Histopathology^{388,392,410}

Histological examination shows a well-demarcated area of psoriasiform epidermal hyperplasia in which the keratinocytes have pale-staining cytoplasm. The epithelium of the adnexa is spared. There are intermittent broad and slender rete pegs, and there is a tendency for the acanthosis to be more prominent centrally. There may be fusion of the acanthotic downgrowths. Usually, there is slight acanthosis of the epidermis, involving one or two rete ridges bordering the area of pale acanthosis (Fig. 31.15).⁴¹⁰

Other epidermal changes include mild spongiosis, exocytosis of neutrophils that may form tiny intraepidermal microabscesses, and thinning of the suprapapillary plates. The epidermal surface shows parakeratotic scale and sometimes focal pustulation. The cytoplasm of the basal cells may not be as pale as that of the other keratinocytes: it is often devoid of melanin pigment, although melanocytes are present.⁴¹¹ A pigmented variant with dendritic melanocytes has been reported.⁴¹² Cellular atypia is a rare occurrence.⁴¹³

Several recent papers have noted an association between clear cell acanthoma and syringofibroadenoma (see Chapter 33), with intermingling of these two lesions.^{414,415} In one study, 19% of 47 cases demonstrated this association.⁴¹⁵ Both lesions showed immunoreactivity for epithelial membrane antigen, whereas ductal luminal cells and, to a lesser extent, the epithelial cords of the syringofibroadenoma component uniquely demonstrated CK19 and carcinoembryonic antigen positivity.⁴¹⁵ It has been proposed that these two lesions may have a shared pathogenesis or represent a spectrum of reactive change involving the eccrine ductal apparatus.⁴¹⁵

The dermal papillae are edematous, with increased vascularity and a mixed inflammatory cell infiltrate that includes a variable proportion of lymphocytes, plasma cells, and neutrophils. In several cases, the sweat ducts have been dilated, and rarely they may be hyperplastic.

A periodic acid–Schiff (PAS) stain, with and without diastase, will confirm the presence of abundant glycogen in the pale cells. Electron

Figure 31.15 (A) Clear cell acanthoma. (B) The lesion is acanthotic, with pale-staining keratinocytes, except at the periphery of the lesion where they appear normal. (H&E) (C) The cells stain with the PAS stain.

microscopy has also confirmed that the keratinocytes contain glycogen.^{416,417} Langerhans cells are also abundant.^{398,418} Immunohistochemistry shows that the cells contain keratin and involucrin but not carcinoembryonic antigen.⁴¹⁹

It has been suggested that there is a distinct tissue reaction – pale cell acanthosis (clear cell acanthosis) – characterized by the presence of pale cells in an acanthotic epidermis.⁴²⁰ This histological pattern can be seen not only in clear cell acanthoma but also in some seborrheic keratoses, usually the clonal subtype, and rarely in verruca vulgaris. The lesion reported as a cystic clear cell acanthoma may represent this tissue reaction occurring in an epidermal cyst or dilated follicle.⁴²¹

On dermoscopy, there is some resemblance to psoriasis, with a squamous surface and translucent collarette.⁴²² There are dilated capillary loops, with a mainly perpendicular orientation to the skin surface.⁴²² Another description highlights multiple dotted vessels in ‘string of pearls’ distribution, forming a reticulated arrangement on a whitish background.⁴²³

Differential diagnosis

The microscopic features of clear cell acanthoma are unique. Lesions can closely resemble psoriasis, but the sharp demarcation from adjacent epidermis and adnexal sparing are features not encountered in psoriasis. Seborrheic keratoses lack pale-appearing keratinocytes, possess pseudohorn cysts, and are often hyperkeratotic and hypergranulotic. Furthermore, they generally do not show the sharp demarcation that is the hallmark of clear cell acanthoma. Eccrine poroma can have similar clinical features, including a location on the distal extremities, and microscopically, sharp demarcation of tumor from adjacent epidermis is also a characteristic of poromas. However, in contrast to clear cell acanthoma, these lesions are typically composed of small, close-set, basaloid cells.

CLEAR CELL PAPULOSIS

Clear cell papulosis is an exceedingly rare condition characterized by multiple white papules on the face, chest, abdomen, or lumbar region of young women and boys.^{424–429} There is a predisposition for persons of Asian or Hispanic descent.⁴³⁰ Some lesions may develop along the ‘milk lines’. The lesions measure 2–10 mm in size. The number of lesions has ranged from 5 to more than 100. It has been suggested that there may be some histogenetic relationship with Toker’s clear cells of the nipple and that cases reported away from the ‘milk lines’ may be a different entity.⁴³¹

There is no known treatment.⁴²⁹ One study indicated that these asymptomatic lesions tend to undergo at least partial regression in many cases.⁴³²

Histopathology

The epidermis is mildly acanthotic with a slightly disorganized arrangement of the epidermal cells. The characteristic feature is the presence of clear cells scattered mainly among the basal cells, with a few cells in the malpighian layer. The cells are larger than the adjacent keratinocytes. These changes can be subtle and easily missed; therefore, clinical suspicion is often important to permit definitive diagnosis.⁴³³ The clear cells are variably stained by the PAS, mucicarmine, Alcian blue, and colloidal iron methods (Fig. 31.16). A characteristic feature is the positive immunostaining for gross cystic disease fluid protein-15 (GCDFP).⁴²⁴ They also stain positively for cytokeratin 7, CAM5.2, epithelial membrane antigen (EMA), and carcinoembryonic antigen (CEA), but they are negative for CD1a and S100 protein.^{430,434}

The clear cells in pagetoid dyskeratosis, an incidental histological finding in a variety of lesions, are found at a higher level in the epidermis (see p. 311). They do not stain with the PAS or mucicarmine methods.

Figure 31.16 Clear cell papulosis. Clear cells are present in or near the epidermal basilar layer. In this example, they appear to contain mucin, which can be demonstrated on staining with mucicarmine, Alcian blue, or colloidal iron. (H&E)

LARGE CELL ACANTHOMA

Large cell acanthoma occurs as a sharply demarcated, scaly, often lightly pigmented patch, approximately 3–10 mm in diameter, on the sun-exposed skin of middle-aged and elderly individuals.^{435–437} Conjunctival lesions have been reported.^{438,439} It is usually solitary. Clinically, it resembles a seborrheic or actinic keratosis. Large cell acanthoma is thought to comprise sunlight-induced clones of abnormal cells, without a tendency to malignancy.^{435,440} However, the author has seen several cases with bowenoid transformation (see later). As such, it is a distinctive condition^{441–443} and not a variant of solar lentigo, as proposed by Roewert and Ackerman⁴⁴⁴ and others.⁴⁴⁵ Human papillomavirus type 6 (HPV-6) has been isolated from lesional skin in a patient with multiple large cell acanthomas.⁴⁴⁶

Histopathology^{435,436}

There is epidermal thickening caused by the enlargement of keratinocytes to approximately twice their normal size (Fig. 31.17). There is also a proportional increase in nuclear size. The lesions are sharply demarcated from the adjacent normal keratinocytes; the adnexal epithelium within a lesion is usually spared. Other features include orthokeratosis, a prominent granular layer, mild papillomatosis, mild basal pigmentation, and some downward budding of the rete ridges.⁴⁴³ Occasionally, there is a focal lichenoid inflammatory cell infiltrate. Atypia may develop in large cell acanthoma; only rarely is this bowenoid. In a study of one lesion from the conjunctiva, there was a low Ki-67 proliferation index (compared with dysplasias and papillomas) and positivity for p53; cytokeratin expression was similar to that in normal conjunctiva, except for full-thickness CK14 expression and CK negativity.⁴³⁹

EPIDERMAL DYSPLASIAS

The epidermal dysplasias have the potential for malignant transformation. This group includes actinic (solar) keratosis, actinic cheilitis, arsenical keratoses, and PUVA keratosis.

ACTINIC KERATOSIS

Actinic (solar) keratoses present clinically as circumscribed scaly erythematous lesions, usually less than 1 cm in diameter, on the

Figure 31.17 Large cell acanthoma. (A) The keratinocytes are larger than usual, and the granular layer is thickened. Normal epidermis is present at the edge of the photograph. (B) There is mild basal cell atypia. There would be parakeratosis overlying a solar keratosis. There is orthokeratosis here. (H&E)

sun-exposed skin of older individuals.^{447–450} The face, ears, scalp, hands, and forearms are sites of predilection.⁴⁵¹ In sunbed users, punctate dysplastic keratoses have developed, predominantly on the plantar aspect of the feet.⁴⁵² In Australia, actinic keratoses are found in 40–60% of people aged 40 years or older.^{453,454} They develop most often in those with a fair complexion, who do not tan readily.⁴⁵⁵ They may also develop in lesions of vitiligo.⁴⁵⁶ In contrast, in England the prevalence of actinic keratoses is approximately 15% for men and 6% for women.⁴⁵⁷ The prevalence is also low in Italy and Japan.⁴⁵⁸

Actinic keratoses may remit, or remain unchanged for many years.^{459–462} It has been stated that 8–20% gradually transform into squamous cell carcinoma if left untreated.^{447,463,464} The hyperplastic variant appears to have a relatively high rate of malignant transformation.⁴⁶⁵ In one study, the annual incidence rate of malignant transformation of a solar keratosis was less than 0.25% for each keratosis,⁴⁶⁶ but this study has been criticized on several grounds.^{467,468} In a systematic literature search by Werner *et al.*, progression rates of actinic keratoses to squamous cell carcinoma ranged from 0 to 0.075% per lesion-year, with a risk of up to 0.53% per lesion in patients with non-melanoma skin cancer.⁴⁶⁹ Rates of regression of single lesions after 1 year range from 15 to 63%, but a portion of these regressed lesions recur 1 year after regression.⁴⁶⁹ Patients with solar keratoses on the trunk or lower extremities are at high risk for skin cancer development.⁴⁷⁰

Ackerman and others have proposed that actinic keratoses are morphological expressions of squamous cell carcinoma (see p. 816),^{471–474} whereas Cockerell has suggested that actinic (solar) keratoses be renamed ‘keratinocytic intraepidermal neoplasia’ or ‘solar keratotic intraepidermal SCC’.^{475,476} It is difficult to envisage clinicians embracing this latter terminology. This trend to abandon precursor diagnoses in favor of the worst scenario outcome has important implications for patient management and patients’ peace of mind, not to mention its conflict with traditional views of the stepwise (multistage) progression of neoplasia.^{477–482} A report published in 2008 suggests that Bowen’s disease and actinic keratoses are derived from different cells. Basal cells appear to play a role in the histogenesis of actinic keratosis but not Bowen’s disease.⁴⁸³

Several clinical variants of actinic keratosis have been described. In the *hyperplastic* (hypertrophic) form, found almost exclusively on the dorsum of the hands and the forearms, individual lesions are quite thick.^{484,485} The changes probably result in part from the superadded changes caused by rubbing and scratching. They may be overdiagnosed clinically as squamous cell carcinoma.⁴⁸⁴ The *acantholytic* variant clinically mimics a basal cell carcinoma. It is sometimes present in lesions not responding to local therapy, but whether it is the cause of the treatment failure or the result of treatment is speculative. The spreading *pigmented* actinic keratosis is a brown patch or plaque, usually greater than 1 cm in diameter, that tends to spread centrifugally.^{486,487} Some cases appear to represent the collision of an actinic keratosis and solar lentigo.⁴⁸⁸ This lesion can be associated with an adjacent melanoma *in situ*.⁴⁸⁹ The cheeks and forehead are sites of predilection. The *lichenoid* actinic keratosis (not to be confused with the lichen planus-like keratosis) is not usually distinctive, although sometimes local irritation is noted.⁴⁹⁰

Cumulative exposure to sunlight appears to be important in the etiology. Intermittent, intense ultraviolet (UV) exposure in childhood, manifest as sunburn, is also strongly associated with the prevalence of actinic keratoses.⁴⁹¹ It has been regarded as an ‘occupational and environmental disorder’.⁴⁹² Despite educational programs, a significant number of individuals still experience sunburns.⁴⁹³ It remains to be seen whether the use of sunless tanning products will result in safer sun protection strategies.⁴⁹⁴ Work has demonstrated that *Betapapillomavirus* infection in combination with key risk factors increases the risk of actinic keratoses.⁴⁹⁵ These viruses were previously categorized as epidermodysplasia verruciformis (EV) – HPV types. Abnormalities in DNA synthesis in keratinocytes in the skin around the lesion suggest

that there is a gradual stepwise progression from sun-damaged epidermis to clinically obvious keratoses and eventually to squamous cell carcinoma.^{495,496} This occurs at both the morphological and the molecular level.⁴⁹⁷ The long-term use of hydroxyurea can also produce squamous dysplasia, which may be a precursor of multiple squamous cell carcinomas.⁴⁹⁸ The keratinocytes in solar keratoses, like those in squamous cell carcinomas, lose various surface carbohydrates.⁴⁹⁹

Approximately 50% of actinic keratoses and squamous cell carcinomas show overexpression of cyclin D protein as well as p53 positivity.^{500–505} Bcl-2 may be increased in actinic keratoses.⁵⁰⁶ The presence of these regulatory markers correlates with the severity of the solar elastosis, suggesting that the grade of solar elastosis is a helpful marker of epithelial UV damage.⁵⁰⁷ Tenascin expression is increased in the stroma beneath actinic keratoses, and this increases with the atypia.⁵⁰⁸ Activated *ras* genes are found in a small percentage of cases.⁵⁰⁹ There is also diminished expression of tumor suppressor genes.⁵¹⁰ However, no genetic susceptibility to actinic keratoses has been found.⁵⁰⁴

Therapies for actinic keratoses include cryosurgery,^{511,512} 5-fluorouracil, diclofenac, imiquimod (not licensed for this purpose in some countries), resiquimod (still undergoing evaluation),⁵¹³ curettage, and photodynamic therapy. Long-term treatment of photoaged human skin with topical retinoic acid improves epidermal cell atypia.^{514,515} Facial resurfacing using the carbon dioxide laser, a 30% trichloroacetic acid peel, or 5% fluorouracil cream has been shown to reduce the subsequent development of actinic keratoses and skin cancers compared with a control group.⁵¹⁶ In one study, 48.2% of incompletely removed actinic keratoses recurred, with one recurring as a squamous cell carcinoma.⁵¹⁷

Histopathology⁵¹⁸

Diagnostic biopsy is undertaken in only a small percentage of actinic keratoses diagnosed clinically.⁴⁵³ The clinical accuracy in the recognition of actinic keratoses varies from 74 to 94%.⁵¹⁹ The usual actinic keratosis is characterized by focal parakeratosis, with loss of the underlying granular layer and a slightly thickened epidermis with some irregular downward buds (Fig. 31.18). Uncommonly, the epidermis is thinner than normal. In all cases, there is variable loss of the normal orderly stratified arrangement of the epidermis; this is associated with cytological atypia of keratinocytes, which varies from slight to extreme. The term ‘bowenoid keratosis’ may be used when the atypia is close to full thickness.⁴⁸⁶ This variant differs markedly from the ‘*de novo*’ form of Bowen’s disease (see later). Sometimes the dysplastic epithelium shows suprabasal cleft formation (see later).^{447,520,521} There is often a sharp slanting border between the normal epidermis of the acrotrichia and acrosyringia and the parakeratotic atypical epithelium of the keratosis.⁵²² However, dysplastic epithelium may involve the infundibular portion of the hair follicle.^{522–524} The parakeratotic scale may sometimes pile up to form a cutaneous horn.⁴⁴⁷ Large keratohyaline granules are sometimes present in actinic keratoses.⁵²⁵

The dermal changes include actinic elastosis, which is usually quite severe, and a variable, but usually mild, chronic inflammatory cell infiltrate.⁴⁴⁷ As mentioned previously, the grade of solar elastosis is a marker of epithelial UV damage.⁵⁰⁷ Inflammatory keratoses may develop during chemotherapy of malignant disease with fluorouracil and its analogues.^{526–529} There is vascular telangiectasia and a moderately heavy mixed inflammatory cell infiltrate in the upper dermis. Inflammation of actinic keratoses has also been reported following therapy with sorafenib, a multitargeted tyrosine kinase inhibitor.⁵³⁰ Some actinic keratoses progress to squamous cell carcinoma with this therapy.⁵³⁰ An inflammatory response is also present in actinic keratoses before they progress to squamous cell carcinomas, unrelated to any therapies.⁵³¹ The inflammation subsides rapidly following this conversion.⁵³¹

Figure 31.18 Solar keratosis. (A) There is mild to moderate atypia of keratinocytes and some pallor of cells. There is overlying parakeratosis. (B) This example shows atypical basilar epithelium, overlaid by bland-appearing epithelium that derives from relatively spared follicular units – an example of the 'umbrella effect'. (H&E)

In the *hyperplastic (hypertrophic) form*, there is prominent orthokeratosis with alternating parakeratosis.⁴⁸⁴ The epidermis usually shows irregular psoriasiform hyperplasia, and sometimes there is mild papillomatosis. Dysplastic changes are sometimes minimal and confined to the basal layer.⁴⁸⁵ The presence of vertical collagen bundles and some dilated vessels in the papillary dermis is evidence that these lesions represent actinic keratoses, with superimposed changes due to rubbing or scratching (lichen simplex chronicus).⁴⁸⁴ Hyperplastic (hypertrophic) forms have a higher resistance to apoptotic stimuli compared to atrophic variants.⁵³²

In the closely related *proliferative variant*, there is a strong propensity to transform into an invasive squamous cell carcinoma.⁵³³ Nests of atypical cells extend as finger-like projections into the upper dermis. It has a pseudo-infiltrative appearance. Extension down hair follicles and, less frequently, acrosyringia may be present. A heavy inflammatory cell infiltrate of lymphocytes and some plasma cells is often present.⁵³³

In the *atrophic actinic keratosis*, the epidermis is thin, with only several layers of keratinocytes. Atypia is usually limited to the basal layer. There is usually overlying hyperkeratosis and focal parakeratosis.

Figure 31.19 Lichenoid actinic keratosis. In addition to basilar keratinocyte atypia, there are vacuolar changes, apoptotic keratinocytes, and a band-like chronic inflammatory infiltrate. (H&E)

In the *acantholytic variant*, there are clefts, usually suprabasal in location, although the change may be more widespread, with acantholytic and dyskeratotic cells resulting from anaplastic/atypical changes producing disrupted intercellular bridges.⁴⁵⁰

In the *pigmented variant*, there is excess melanin in the lower epidermis, usually in both keratinocytes and melanocytes but sometimes only in one or the other.⁴⁸⁶ Melanophages are usually found in the papillary dermis.⁴⁸⁶

The *bowenoid actinic keratosis* is a controversial entity. It is usually a focal change, indistinguishable from Bowen's disease. Overlying parakeratosis is often present. The author rarely uses the term these days, and only as a 'fence-sitting' diagnosis on 2-mm biopsies (or smaller). The pagetoid variant of actinic keratosis is closely related.⁵³⁴

In *lichenoid actinic keratoses*, there is a superficial, often band-like, chronic inflammatory cell infiltrate, with occasional apoptotic keratinocytes in the basal layer and some basal vacuolar change (Fig. 31.19).⁴⁹⁰ The acral keratotic lesions with a lichenoid infiltrate, reported as a possible manifestation of graft-versus-host disease, may have been a manifestation of HPV infection because wart-virus features sometimes remit in the presence of a lichenoid infiltrate.⁵³⁵

The *lymphomatoid keratosis* is mentioned here for completeness, although it does not have epidermal atypia or lichenoid (interface) changes.⁵³⁶ It is an epidermotropic subtype of cutaneous lymphoid hyperplasia with a dense, band-like infiltrate of lymphocytes beneath a sometimes hyperplastic epidermis. The infiltrate contains both T and B lymphocytes.⁵³⁷ It looks like a lichen planus-like keratosis but with epidermotropism rather than basal cell death.⁵³⁶

In all types of actinic keratoses in immunosuppressed patients, there is usually marked atypia of the keratinocytes;⁵³⁸ multinucleate forms may be present.⁵³⁸ Confluent parakeratosis and verruciform changes may also occur.^{539,540}

It is sometimes a matter of personal judgment whether a lesion is considered to show early squamous cell carcinomatous change or not.⁵⁴¹ The protrusion of atypical cells into the reticular dermis and the detachment of individual nests of keratinocytes from the lower layers of the epidermis are criteria used to diagnose invasive transformation.⁵⁴¹ Step sections are important in small biopsies initially regarded as solar keratosis. More significant pathology may emerge in the deeper sections.^{542,543} Despite these difficulties, there is a good concordance in the diagnosis of these borderline cases among

dermatopathologists.⁵⁴⁴ An AgNOR analysis (see p. 854) may identify actinic keratoses with high proliferative activity and an increased tendency to develop into invasive squamous cell carcinoma.⁵⁴⁵

Confocal laser microscopic imaging of actinic keratoses has been used.⁵⁴⁶ A diagnosis of actinic keratosis can often be made by this technique.⁵⁴⁷ Fluorescence techniques are not a suitable method of distinguishing keratinocytic atypias from normal skin.⁵⁴⁸

Electron microscopy

Ultrastructural studies suggest that the hyperpigmentation in the pigmented variant is due to enhanced melanosome formation and distribution and not to a block in the transfer of melanosomes to keratinocytes.⁴⁸⁷

Differential diagnosis

Actinic keratoses showing full-thickness atypia can closely resemble Bowen's disease; in fact, a reliable histopathologic distinction between the two can be difficult to achieve. One study showed a similar histochemical profile for Bowen's disease and bowenoid actinic keratosis when using the markers p53 and p16.⁵⁴⁹ Lumican is a keratan sulfate proteoglycan that, among other functions, may regulate epithelial cell migration and tissue repair. A study of lumican using direct immunofluorescence and *in situ* hybridization methods showed expression of the protein in more than 90% of Bowen's disease and in none of the studied cases of actinic keratosis;⁵⁵⁰ this may prove to be a useful stain for the differential diagnosis of these lesions. Actinic keratoses must also be distinguished from the **epidermal dysmaturation** that may be seen following chemotherapy or transplantation.⁵⁵¹ It is a histological diagnosis characterized by disruption of keratinocyte maturation, loss of polarity, widened intercellular spaces, irregular large nuclei, mid-epidermal mitotic figures, and apoptosis.^{552,553} Colchicine intoxication can also result in dysmaturation with metaphase-arrested keratinocytes and basal vacuolar change.⁵⁵⁴

Actinic keratosis can resemble a variety of other conditions, including acantholytic dermatoses (Darier disease or Grover disease); benign lichenoid keratosis; and, rarely, other interface dermatoses (especially when they are only partly sampled), such as lupus erythematosus, irritated seborrheic keratosis (basosquamous acanthoma), solar lentigo, large cell acanthoma, lentigo maligna, superficial basal cell carcinoma, and porokeratosis. A key to the recognition of actinic keratosis is keratinocyte atypia that involves the basilar layer of the epidermis. This feature aids in distinguishing actinic keratoses from other acantholytic dermatoses, such as Grover's disease, acantholytic acanthoma, Darier's disease, or warty dyskeratoma. Benign lichenoid keratoses can closely mimic actinic keratoses and can show limited degrees of atypia, at times making distinction from lichenoid actinic keratoses difficult. However, the basilar atypia in benign lichenoid keratoses is usually not only mild but also confined to areas of most intense inflammation. Evidence for origin in a lentigo or seborrheic keratosis is also frequently observed in benign lichenoid keratosis. Lichenoid actinic keratoses usually show unequivocal basilar atypia, often extending beyond foci of band-like inflammation, and suprabasilar acantholysis may be present.

Forms of lupus erythematosus have been included in the differential diagnosis of actinic keratoses, particularly the atrophic variety. This is not usually a difficult differential problem, due to the lack of keratinocyte atypia in most examples of lupus erythematosus and the presence of other features not generally found in actinic keratoses: orthokeratosis with follicular plugging, distinctive thickening of the basement membrane zone, dermal mucin deposition, and periadnexal inflammation. The difficulties in distinguishing hypertrophic actinic keratoses from some irritated seborrheic keratoses (basosquamous acanthomas), especially those that occur in elderly individuals, were discussed previously. Careful attention to cytologic detail is important,

particularly with regard to basilar keratinocyte atypia, the presence of which favors hypertrophic actinic keratosis. However, occasional cases are difficult to categorize, particularly in superficial biopsy specimens, and re-excision may be warranted in those circumstances. The large cell acanthoma is a controversial lesion that is now widely regarded as a variant of solar lentigo, although some interpret it as a type of actinic keratosis. Solar lentigo, and even lentigo maligna, may be associated with degrees of keratinocyte atypia; similarly, actinic keratoses may be accompanied by lentiginous changes and/or junctional melanocytic hyperplasia. In such circumstances, a judgment must be made regarding which abnormal cell type predominates. This can sometimes be aided by immunohistochemical staining for keratin, S100 protein, or particularly melan-A. Proliferation of atypical melanocytes along outer root sheaths of hair follicles favors lentigo maligna. Clinical data can also be of help, although a spreading pigmented actinic keratosis can easily be confused with lentigo maligna, and in fact these two lesions can sometimes be juxtaposed.

Exaggerated or broad-based basilar budding of actinic keratosis can occasionally be difficult to distinguish from superficial basal cell carcinoma. Islands of the latter tend to show exaggerated peripheral palisading of nuclei or cleft-like spaces separating them from the underlying dermis, but these changes are not always obvious. Immunohistochemical staining for BerEP4 or bcl-2 has been reported to be helpful in this regard; both markers are positive in superficial basal cell carcinomas and negative in actinic keratoses. Differentiation of actinic keratosis from forms of porokeratosis can be a challenge because a cornoid lamella – the parakeratotic column that serves as the diagnostic hallmark for porokeratosis – can also occur in actinic keratosis, and degrees of keratinocyte atypia are also observed in porokeratosis. However, keratinocyte atypia in porokeratosis is concentrated at the base of cornoid lamellae (representing an abnormal clone of keratinocytes), whereas the atypia in actinic keratoses tends to be more radially extensive and not confined to the vicinity of the narrow parakeratotic columns.

On dermoscopy, the pigmented actinic keratosis has a striking similarity to lentigo maligna.^{555,556} This was also the conclusion in a study of 89 facial pigmented lesions, which suggested that histopathology remains the gold standard for accurate diagnosis of these lesions.⁵⁵⁷

ACTINIC CHEILITIS

Actinic cheilitis (solar cheilosis, actinic keratosis of the lip) is a premalignant condition seen predominantly on the vermilion part of the lower lip. It results from chronic exposure to sunlight,⁵⁵⁸ although smoking and chronic irritation may also contribute.⁵⁵⁹ There are dry, whitish-gray scaly plaques in which areas of erythema, erosions, and ulceration may develop.⁵⁵⁸ The whitish areas were known in the past as leukoplakia.⁵⁶⁰ Large areas of the lower lip may be affected. Squamous cell carcinoma may develop after a latent period of 20–30 years,^{561,562} although the incidence of this transformation is difficult to quantify.⁵⁵⁹ This transformation appears to be related to dysregulation of the signal transducer and activator of transcription-3 (STAT-3), a protein involved in the control of cell proliferation and apoptosis.⁵⁶³ Progressive increases in expression of p53 and the DNA repair protein APE1 are seen with evolution from normal lip mucosa to actinic cheilitis to squamous cell carcinoma of the lip, whereas there is a reduction in expression of other repair proteins (hMSH2 and ERCC1) in epithelial cells of actinic cheilitis and squamous cell carcinoma.⁵⁶⁴

An acute form of actinic cheilitis, characterized by edema, erythema, and erosions, has been recognized.⁵⁶⁰ It is an uncommon response to prolonged exposure to sunlight.

Treatment usually parallels that given for actinic keratoses at other sites and includes cryotherapy, electrosurgery, imiquimod, retinoids,

carbon dioxide laser ablation, and surgical excision.⁵⁶⁵ Photodynamic therapy has also been used successfully.⁵⁶⁵

Histopathology^{560,566}

The lesions show alternating areas of orthokeratosis and parakeratosis. The epidermis may be hyperplastic or atrophic. Other features are disordered maturation of epidermal cells, increased mitotic activity, and variable cytological atypia.⁵⁶¹ Sometimes foci of severe atypia are found when the entire vermilion is removed, even though the biopsy showed milder changes.⁵⁶⁷ Squamous cell carcinoma may develop in areas of marked atypia. Cytokeratin expression in actinic cheilitis is not related to the degree of dysplasia.⁵⁶⁸ Langerhans cell hyperplasia is present in lesions of actinic cheilitis compared to normal lip mucosa; no significant differences in density of these cells is seen among different degrees of dysplasia.⁵⁶⁹ Expression of the integrins β_1 , β_4 , and α_3 is reduced in actinic cheilitis and absent in superficially invasive squamous cell carcinomas; the basement membrane protein laminin-5 (as assessed by the Ln-5 γ_2 chain) is negative in actinic cheilitis but positive in the invasive front of the superficially invasive tumors.⁵⁷⁰

There is prominent solar elastosis of the submucosal connective tissue, some vascular telangiectasia, and a mild to moderate infiltrate of chronic inflammatory cells. Plasma cells are usually prominent, particularly beneath areas of ulceration.⁵⁶⁶ An intense inflammatory cell infiltrate is often predictive of an adjacent invasive squamous cell carcinoma.⁵⁷¹ Densities of mast cells, eosinophils, and microvessels increase with tumor progression, and there is evidence that microvessel density may be a predictor of cervical lymph node metastasis in squamous cell carcinomas of the lip arising in this setting.⁵⁷²

Actinic cheilitis and Bowen's disease both need to be distinguished from **pagetoid dyskeratosis**, which has been found as an incidental histological feature in more than 40% of specimens from the lip.⁵⁷³ It is composed of large keratinocytes with a condensed nucleus, a clear halo, and abundant pale cytoplasm.⁵⁷³ This change is not confined to the lips (see p. 311).^{574,575}

Reflectance confocal microscopy of actinic cheilitis shows cytologic atypia with an atypical honeycomb pattern of the involved epidermis; marked inflammation can be a confounding diagnostic feature.⁵⁷⁶

ARSENICAL KERATOSES

For more than a century, inorganic arsenic was used in the treatment of many diverse conditions.⁵⁷⁷ The recognition of its adverse effects, and its replacement by more effective therapeutic agents, has led to a marked reduction in the incidence of arsenic-related conditions.⁵⁷⁸ However, there is a high arsenic content in some drinking waters and naturopathic medicines.⁵⁷⁹⁻⁵⁸⁵ Chronic arsenic poisoning is a worldwide public health problem,⁵⁸⁶ it is particularly prevalent in Bangladesh.⁵⁸⁷

The best-known effect of chronic arsenicism is cutaneous pigmentation, which may be diffuse or of 'raindrop' type.⁵⁸⁸ More than 40% of affected individuals develop keratoses on the palms and soles, and sometimes this is associated with a mild diffuse keratoderma.⁵⁸⁸ Hyperkeratosis on the sole is the most sensitive marker for the detection of arsenicism at an early stage.⁵⁸⁹ There is an increased incidence of multiple skin cancers, which include Bowen's disease, basal cell carcinomas, and squamous cell carcinomas.^{583,590,591} The lesions are sometimes quite exophytic in appearance. Visceral cancers, particularly involving the lung and genitourinary system, may also be found.⁵⁹²

Many arsenical skin cancers express p53, although arsenic-related basal cell carcinomas express it less intensely than sporadic ones.⁵⁹³ It is also found in perilesional skin.^{594,595} The expression of p53 is reduced after UVB therapy.⁵⁹⁶ Arsenic also appears to produce defective expression of β_1 -integrins in arsenical keratoses.⁵⁹⁷

Figure 31.20 Tar keratosis. There is pronounced hyperkeratosis, papillomatosis, and acanthosis. (H&E)

Histopathology^{579,580}

Arsenical keratoses are of the hyperkeratotic type. Sometimes there is prominent hyperkeratosis and papillomatosis but no atypia. These lesions have a superficial resemblance to the hyperkeratotic type of seborrheic keratosis. Similar lesions follow exposure to tar (Fig. 31.20).⁵⁹⁸ In other cases, there is mild atypia resembling the hyperkeratotic variant of actinic keratosis.

In some lesions of Bowen's disease related to exposure to arsenic, there may be areas resembling seborrheic keratosis, superficial basal cell carcinoma, or intraepidermal epithelioma of Jadassohn. Invasive carcinomas arising in Bowen's disease show the nonkeratinizing pattern of squamous cell carcinoma, sometimes with areas of appendageal differentiation (see later).

The basal cell carcinomas that develop may be of solid or (multifocal) superficial type.

PUVA KERATOSIS

A PUVA keratosis is a distinctive form of keratosis, often found on non-sun-exposed skin of patients who have received long-term treatment with psoralens and ultraviolet-A radiation (PUVA).⁵⁹⁹ It is a raised papule with a broad base and a scaly surface, often with a warty appearance. There is an increased risk of developing non-melanoma skin cancer, particularly with long-term, high-dose exposure.⁶⁰⁰⁻⁶⁰² Punctate keratoses on the hands and feet are a rare complication of PUVA therapy.⁶⁰³

Histopathology

There is a variable degree of acanthosis, orthokeratosis, and parakeratosis. Papillomatosis is present in one-half of the lesions. PUVA keratoses differ from actinic keratoses by their paucity of atypical cells and an absence of solar elastosis.⁵⁹⁹ The lesions reported as disseminated hypopigmented keratoses developed in young patients who had previously received PUVA therapy.⁶⁰⁴ They had some histological resemblance to stucco keratoses (see p. 826).⁶⁰⁴

INTRAEPIDERMAL CARCINOMAS

Although the term 'intraepidermal carcinoma' is often used synonymously with Bowen's disease, it is used here in a broader sense to

include not only carcinoma *in situ* of the skin (Bowen's disease) and penis (erythroplasia of Queyrat) but also intraepidermal epithelioma of Jadassohn, a controversial entity of disputed histogenesis. Paget's disease is sometimes included in this category because of the presence of cytologically malignant cells within the epidermis. Paget's disease is discussed with the appendageal tumors on page 961.

BOWEN'S DISEASE

Bowen's disease is a clinical expression of squamous cell carcinoma *in situ* of the skin.⁶⁰⁵ It presents as an asymptomatic well-defined erythematous scaly plaque, which expands centrifugally. Verrucous, nodular, eroded, and pigmented variants occur.⁶⁰⁶⁻⁶¹⁰ Many of the pigmented lesions reported in the anogenital area as Bowen's disease⁶¹¹⁻⁶¹³ would now be regarded as examples of bowenoid papulosis⁶¹⁴ (see p. 738).

Bowen's disease has a predilection for the sun-exposed areas (particularly the face and legs) of fair-skinned older individuals.⁶¹⁵⁻⁶¹⁷ It is uncommon in black people,⁶¹⁸ in whom it is found more often on areas of the skin that are not exposed to the sun.⁶¹⁹ Its incidence in the Canadian province of Alberta, during the 5-year period from 1996 to 2000, was 22.4 lesions per 100,000 women and 27.8 per 100,000 men.⁶²⁰ Lesions may also develop on the trunk,⁶²¹ the vulva; and, rarely, the nail bed,⁶²²⁻⁶²⁹ where it may be polydactylous,⁶³⁰ lip;⁶³¹ nipple;⁶³² palm;⁶³³⁻⁶³⁵ sole;⁶³⁶ web spaces of the feet;⁶³⁷ and the margin of an eyelid.^{638,639} In one case, Bowen's disease of the nail bed presented as a longitudinal melanonychia.⁶⁴⁰ In another, there was periungual Bowen's disease and vulval intraepithelial neoplasia (VIN) concordant for the same HPV types (HPV-34 and HPV-21).⁶⁴¹ Bowen's disease has been reported in the wall of an epidermoid, and a follicular cyst,^{642,643} in a lesion of porokeratosis of Mibelli,⁶⁴⁴ above a scar,⁶⁴⁵ in erythema ab igne,⁶⁴⁶ in a smallpox vaccination scar,⁶⁴⁷ and in seborrheic keratoses (see p. 801).

Several investigators have proposed that Bowen's disease should be considered a skin marker for internal malignant disease,⁶⁴⁸⁻⁶⁵² although more recent studies have shown no evidence for this association.⁶⁵³⁻⁶⁵⁵ However, patients with Bowen's disease have the same increased risk of developing a subsequent skin cancer as do those with invasive squamous cell carcinoma.⁶⁵⁶

Invasive carcinoma develops in up to 8% of untreated cases.^{657,658} This complication, which is not well recognized, is characterized by the development of a rapidly growing tumor, 1–15 cm in diameter, in a pre-existing scaly lesion.⁶⁵⁸ It appears to be more common in older people and in immunocompromised patients.⁶⁵⁹ Invasive squamous cell carcinoma is a not uncommon complication of the diffuse variant of Bowen's disease, associated with extensive adnexal extension of the disease.⁶⁶⁰ The invasive tumor has metastatic potential, which has been stated to be as high as 13%,⁶⁵⁸ although this would appear to be an overestimation of the risk.^{657,661-663} Spontaneous complete regression of Bowen's disease has also been reported.⁶⁶⁴

Several factors have been implicated in the etiology of Bowen's disease, including prolonged exposure to solar radiation, the ingestion of arsenic,^{588,648,665} and infection with HPV.⁶⁶⁶ Whereas HPV-16, HPV-18, and, to a lesser extent, HPV-31, -33, -39, -52, -67, and -82 have been detected in Bowen's disease of the genital region and its precursors,⁶⁶⁷⁻⁶⁶⁹ there are now several reports of nongenital Bowen's disease related to infections with HPV-2,⁶⁷⁰ -16,⁶⁷¹⁻⁶⁷⁵ -27,⁶⁷⁶ -33,^{676,677} -34,^{678,679} -56,^{677,680,681} -58,⁶⁸² -59,⁶⁸³ and -76.⁶⁷⁶ Epidermodysplasia verruciformis-related HPV types (*Betapapillomavirus*) are associated with the pathogenesis of Bowen's disease as well as the better known mucosal strains of HPV.⁶⁸⁴ There is a clear association between anal intraepithelial neoplasia and high-risk HPV types in patients with HIV infection.^{685,686} It is an important precursor of invasive squamous cell carcinoma.^{687,688} Bowen's disease is a rare complication of the treatment of psoriasis

with PUVA.⁶⁸⁹⁻⁶⁹¹ It has been reported in a patient who performed arc welding.⁶⁹²

Bowenoid papulosis (see p. 738) consists of one or more indolent, verrucous papules on the genitalia with a clinical resemblance to condyloma acuminatum and a histological resemblance to Bowen's disease. HPV-16 is the most frequently detected HPV subtype in this condition.⁶⁹³ It usually responds to local therapies, but recurrences and the development of invasive carcinoma have been reported.⁶⁶⁸ The term 'penile intraepithelial neoplasia' (PIN) has been coined to encompass the three preinvasive clinical entities of penile Bowen's disease, erythroplasia of Queyrat, and bowenoid papulosis.⁶⁹⁴

Regarding treatment, cryotherapy is most commonly used. Recurrences take place particularly when adnexal structures are involved. Other treatments include curettage with or without cautery; imiquimod 5% cream (although invasive squamous cell carcinoma has developed in several cases treated with this therapy); photodynamic therapy, usually in conjunction with topical 5-aminolevulinic acid but also with *meta*-tetrahydroxychlorin in cases of vulvar intraepithelial neoplasia,⁶⁹⁵ radiation therapy;⁶⁹⁶ acitretin for multiple arsenical keratoses and Bowen's disease;⁶⁹⁷ and surgical procedures, including Mohs surgery.

Histopathology^{447,698}

Bowen's disease is a form of carcinoma *in situ* and accordingly shows full-thickness involvement of the epidermis, and sometimes the pilosebaceous epithelium, by atypical keratinocytes.⁶⁹⁹⁻⁷⁰¹ This is associated with disorderly maturation of the epidermis, mitoses at different levels, multinucleate keratinocytes, and dyskeratotic cells. Usually, there is loss of the granular layer, with overlying parakeratosis and sometimes hyperkeratosis.

Several histological variants have been described, and more than one of these patterns may be present in different areas of the same lesion.⁶⁹⁸ In the *psoriasiform* pattern, there is regular acanthosis with thickening of the rete ridges and overlying parakeratosis (**Fig. 31.21**).⁶⁹⁸ In the *atrophic* form, there is thinning of the epidermis, which shows full-thickness atypia and disorganization.⁶⁹⁸ There is usually overlying hyperkeratosis and parakeratosis. The *verrucous-hyperkeratotic* type is characterized by hyperkeratosis, papillomatosis, and sometimes intervening pit-like invaginations.⁶⁹⁸ The *papillated* variant, which has sometimes been included with the verrucous-hyperkeratotic type, is an exophytic/endophytic, sometimes keratotic lesion.⁷⁰² A perinuclear halo is present in some of the cells, suggestive of koilocytosis.⁷⁰² The *irregular* variant shows irregular acanthosis and often extensive chronic

Figure 31.21 Bowen's disease. There is full-thickness atypia of the epidermis, which also shows psoriasiform hyperplasia. (H&E)

Figure 31.22 Bowen's disease. The atypical keratinocytes are pale, with a pagetoid appearance. (H&E)

inflammation in the underlying dermis.⁶⁹⁸ In the *pigmented* type, there is melanin in individual tumor cells with melanophages in the underlying dermis.⁶¹⁴ The *pagetoid* variant has nests of cells with pale cytoplasm and thin strands of relatively normal keratinocytes intervening; the basal layer may also be spared (Fig. 31.22). Sometimes this is associated with psoriasiform hyperplasia of the epidermis. *Mucinous* and *sebaceous* metaplasia characterize two other rare histological patterns.⁷⁰³ *Clear cell* change represents outer root sheath differentiation.⁷⁰⁴ HPV types have been identified in this clear cell variant.⁷⁰⁵

As previously mentioned, the atypical epithelium may also involve the pilosebaceous units. This may lead to treatment failure when superficial methods of destruction are used.^{706,707} Involvement of the eccrine ducts is uncommon,^{708,709} and in the author's experience it has usually been confined to cases of Bowen's disease of the temple region.⁷¹⁰

Changes in the underlying dermis include increased vascularity and a variable inflammatory response, which is usually composed of lymphocytes. Occasionally, this has lichenoid features. Partial regression may ensue.⁷¹¹ Small deposits of amyloid may be found in the papillary dermis, particularly in lesions of long standing.⁶⁹⁸

In Bowen's disease, there is a diffuse pattern of staining of the keratinocyte nuclei for PCNA.⁷¹²⁻⁷¹⁵ There is widespread expression of CK10 in almost all cases of Bowen's disease.⁷¹⁶ CD1a⁺ cells are significantly decreased.⁷¹⁷ In clear cell Bowen's disease, the cells express keratins found in the outer root sheath, such as CK13, CK16, and CK15. The cells stain with CAM5.2.⁷⁰⁴ The expression of CK14 may be a marker for tumor progression.⁷¹⁸

Although p16 overexpression is a surrogate marker of HPV E7-mediated catabolism of the regulatory protein pRb in premalignant and malignant lesions of cervical mucosa, its overexpression in cutaneous Bowen's disease is unrelated to HPV status.⁷¹⁹ Its overexpression in Bowen's disease may reflect disruption of the G₁/S checkpoint, resulting in unregulated cell cycle progression.^{719,720}

In the invasive form, there are large islands of nonkeratinizing squamoid cells throughout the dermis.⁶⁵⁸ The cells usually have pale cytoplasm. Basaloid and adnexal differentiation are common patterns.^{658,721,722} The invasive tumor that supervenes is best regarded as a variant of squamous cell carcinoma. Invasion may be facilitated by the production of metalloproteinases that are involved in the destruction of basement membrane.⁷²³ An association between Bowen's disease and Merkel cell carcinoma is well-known.⁷²⁴

Fluorescence diagnosis (based on the property of tissue-emitted fluorescence following application of a photosensitizer) has been used

successfully as a method of diagnosis, especially as a means of following up treated Bowen's disease lesions.⁷²⁵

The term 'Bowen's disease' is no longer used in gynecological pathology, having been replaced in 1986 by the concept of vulvar intraepithelial neoplasia (VIN).⁷²⁶⁻⁷²⁹ Progressive atypia of the epithelium is semiquantified, with VIN I representing atypia confined to the basal third of the epidermis and VIN II corresponding to involvement of from one-third to two-thirds of the epithelium. In VIN III, the atypical cells involve more than two-thirds of the thickness of the epidermis. Bowen's disease therefore corresponds to severe VIN III.⁷³⁰ There has been an attempt to apply this concept, in part, to other areas of the skin.⁷³¹

In 2004, the International Society for the Study of Vulvovaginal Disease abandoned the grading of vulvar intraepithelial neoplasia. Little has been published in the dermatological or pathological literature on this change.^{732,733} The old VIN I is regarded now as representing HPV infection, whereas VIN II and VIN III have been combined to form a warty-basaloid type of VIN to distinguish it from the less common differentiated VIN that remains unchanged in the new nomenclature.⁷³² Whereas squamous cell carcinoma *in situ* is regarded as an acceptable alternative designation to VIN, Bowen's disease is not because it is an eponymous designation with 'no intrinsic definition'.⁷³² Risk factors associated with various vulvar intraepithelial lesions were reviewed in 2005.⁷³⁴

'Vulvar intraepithelial neoplasia' should be distinguished from the entity **multinucleated atypia of the vulva**, in which cells with 2–10 nuclei are found in the cells of the lower layers of the epithelium of the vulva.⁷³⁵ The cells lack hyperchromasia or variation in nuclear size. HPV has not been detected. The nature of this process is uncertain. Parenthetically, the author has seen multinucleate cells in the epidermis of patients who have applied retinoic acid for a long time (unpublished observation).

Rare cases have been reported of metastatic squamous cell carcinoma presenting as epidermotropic bowenoid lesions.⁷³⁶

Attempts have been made to introduce a three-tiered grading system for keratinocytic atypia, similar to the previous system of grading atypia on the vulva and cervix. In an informal trial, dermatopathologists were reliably able to categorize the continuum of keratinocytic atypia with substantial concordance.⁷³⁷⁻⁷³⁹ Keratinocytic intraepithelial neoplasia (KIN) has not yet received much acceptance in the broader community of pathologists and dermatologists. The concept is not supported by experimental work involving cyclin A levels in actinic keratosis and Bowen's disease.⁷⁴⁰

Dermoscopy can be helpful for diagnosing Bowen's disease. It is characterized by glomerular vessels and a scaly surface.⁷⁴¹ A corona of these glomerular vessels surrounding a central hyperkeratotic or crusted area is considered a diagnostic marker of hyperkeratotic Bowen's disease.⁷⁴² In pigmented lesions, small brown globules and/or homogeneous pigmentation are also present.⁷⁴¹ A pattern of brown or gray dots, sometimes forming linear arrangements, together with coiled vessels is considered rather specific for pigmented Bowen's disease.^{743,744}

Electron microscopy⁷⁴⁵

The keratinocytes have large nuclei and nucleoli and a reduced number of desmosomal attachments.⁷⁴⁶ The dyskeratotic cells show an aggregation of cytoplasmic tonofilaments. Occasional apoptotic bodies are present in the intercellular spaces, whereas others have been phagocytosed by neighboring keratinocytes.^{747,748} Cytoplasmic projections of keratinocytes may extend through gaps in the basement membrane.⁷⁴⁵

Differential diagnosis

Bowen's disease differs from **actinic (solar) keratosis** in the full-thickness atypia of the epithelium and in usually sparing the

acrosyringium and sometimes also the basal layer, which is always atypical in actinic keratoses. Both lesions may show aneuploidy of the constituent cells,⁷⁴⁹ and both may express mutant p53 protein and p21.⁷⁵⁰⁻⁷⁵² In solar keratoses, the keratin and involucrin distribution is similar to normal epidermis, whereas in Bowen's disease the keratin distribution is variable.⁷⁵³ In arsenical keratoses, *in situ* carcinoma indistinguishable from Bowen's disease may develop. Lesions of Bowen's disease can also sometimes resemble **seborrheic keratoses**. Both lesions can have plaque-like configurations and horn cysts. Some cases of Bowen's disease can have closely crowded basaloid cells with limited pleomorphism, whereas the irritated seborrheic keratosis (basosquamous acanthoma) with its squamous eddies and loss of cohesion of keratinocytes can have a distinctly atypical appearance. Lesions with overlapping features of Bowen's disease and seborrheic keratosis do occur, particularly in elderly adults, and cases of Bowen's disease deriving from seborrheic keratoses have been reported. Immunohistochemical staining for the tumor suppressor protein p16 can be helpful in distinguishing Bowen's disease from actinic keratosis or seborrheic keratosis. Bowen's disease shows significant staining of atypical cells within the epidermis, with sparing of the basilar layer; actinic keratoses are either negative for p16 or show basilar layer staining, whereas seborrheic keratoses show only weak, focal staining.⁷²⁴ **Clonal seborrheic keratoses** can also mimic pagetoid Bowen's disease. Differentiation can be made when there is a lack of nuclear crowding or mitoses (favoring clonal seborrheic keratosis) and can be further enhanced by immunohistochemical staining for cytokeratin 10 (a marker of suprabasilar keratinocyte differentiation) and bcl-2 (demonstrating inhibition of apoptosis). In contrast to pagetoid Bowen's disease, the intraepidermal nests of clonal seborrheic keratosis are CK10 negative and bcl-2 positive.³²⁹

Bowenoid papulosis of the genitalia is regarded by some as a variant of Bowen's disease of the genitalia. Although the two conditions may be histologically indistinguishable, features that favor a diagnosis of bowenoid papulosis include numerous mitoses in metaphase, small basophilic inclusions in the cytoplasm of the granular layer, and sometimes cells with koilocytic features (Fig. 31.23). Bowenoid atypia, including apoptotic keratinocytes and mitotic figures, can also be seen in verrucae that have been treated with podophyllin, although these changes largely resolve by 72 hours following application.

Based on their immunohistochemical profile (using outer root sheath cytokeratins 1, 10, and 17, as well as CD34 and D2-40), clear cell squamous cell carcinomas associated with Bowen's disease do not show clear-cut evidence of trichilemmal keratinization, in contrast to **trichilemmomas**.⁷⁵⁴ A direct comparison would seem to be indicated to determine whether these markers might be exploited in the distinction of clear cell squamous cell carcinoma from trichilemmal carcinoma.

The pagetoid variant of Bowen's disease is sometimes difficult to distinguish from **Paget's disease** and from ***in situ* superficial spreading melanoma**, particularly if only a small biopsy is available.^{755,756} In these instances, immunoperoxidase markers may be of assistance. Melanoma cells are positive for S100 protein, whereas Paget cells usually demonstrate CEA.⁷⁵⁷ Melanoma cells do not contain cytokeratins, although Paget cells are positive for cytokeratins with a molecular weight of 54 kDa and negative for those of 66 kDa; the reverse applies with the cells in Bowen's disease.⁷⁵⁸ Although cytokeratin 7 (CK7) has been regarded as a specific marker of Paget's disease, it has also been reported in pagetoid Bowen's disease, but not in the other types.⁷⁵⁹ However, Misago *et al.* found that there is heterogeneity in CK7 expression in pagetoid Bowen's disease, depending on the date of manufacture or lot numbers of the antibody, the type of clone employed, and/or the laboratory method (i.e., the ABCV complex system of the Envision system).⁷⁶⁰ Further issues are raised by a case of perianal pagetoid squamous cell carcinoma *in situ* in which the cells expressed CK7, CAM 5.2, and BerEP4 – a staining profile normally

Figure 31.23 Bowenoid papulosis. There is full-thickness atypia, scattered mitoses in metaphase, basophilic inclusions in the granular layer, and koilocytes. (H&E)

associated with extramammary Paget's disease. Diagnosis in this case was aided by negative mucin stains and positive p63 immunostaining (results expected to be positive and negative, respectively, in the atypical cells of extramammary Paget's disease).^{761,762} A recent study showed that significant immunohistochemical expression of cystic fibrosis transmembrane conductance regulator (CFTR), a cAMP-dependent channel found in apocrine glands, is found in most cases of extramammary Paget's disease, whereas this marker is negative in most cases of squamous cell carcinoma *in situ*.⁷⁶³ **Pagetoid dyskeratosis** (see p. 311) differs from Bowen's disease by the presence of scattered pale cells with small pyknotic nuclei in a background of otherwise normal skin.⁵⁷⁴

Finally, **freeze artifact** in tissue that has been briefly fixed in formalin can mimic Bowen's disease by showing extensive intraepidermal vacuolization artifact, but close inspection fails to show the enlarged, hyperchromatic, and pleomorphic nuclei with scattered mitotic figures expected in Bowen's disease.⁷⁶⁴

ERYTHROPLASIA OF QUEYRAT

Erythroplasia of Queyrat is a clinical expression of carcinoma *in situ* of the penis.⁷⁶⁵⁻⁷⁷⁰ It is found most commonly on the glans penis of

uncircumcised males as a sharply circumscribed, asymptomatic, bright red shiny plaque.⁷⁶⁷ It may also arise on the coronal sulcus or the inner surface of the prepuce. As in Bowen's disease, invasive carcinoma may develop in up to 10% of cases of erythroplasia of Queyrat, and such tumors have metastatic potential.⁷⁶⁵

The etiology of this condition has been regarded as multifactorial: chronic irritation, poor hygiene, genital herpes simplex, and infection with HPV have all been incriminated.⁷⁷¹ It has also arisen on a background of Zoon's balanitis.⁷⁷² Interestingly, that patient had been treated with topical pimecrolimus a few weeks before the appearance of the lesion.⁷⁷² In one study, the rare epidermodysplasia verruciformis-associated subtype, HPV-8, was detected in all cases studied.⁷⁷³ A co-infection with other HPV types, particularly HPV-16, HPV-39, and HPV-51, was usually present.⁷⁷³ In a study of 11 patients, all samples were negative for HPV-DNA using a two-step nested PCR technique with MY11/MY09 consensus primers and general GP5⁺/GP6⁺ PCR primers.⁷⁷⁴

Imiquimod 5% cream, topical 5-fluorouracil, cryotherapy, and photodynamic therapy have all been used to treat this condition.^{772,775,776}

Histopathology^{765,766}

The changes are those of a carcinoma *in situ*, as in Bowen's disease.⁷⁷⁷ There are said to be fewer multinucleate and dyskeratotic cells than in Bowen's disease.⁷⁶⁷ The accompanying inflammatory cell infiltrate in the dermis is often rich in plasma cells (Fig. 31.24).⁷⁶⁵

A non-invasive imaging technique known as optical coherence tomography was used to determine that a lesion of erythroplasia of Queyrat was in fact confined to the epidermis and also to confirm successful treatment with topical imiquimod therapy.⁷⁷⁸

Differential diagnosis

Erythroplasia can have a clinical resemblance to Zoon's plasmacellular balanitis. Generally, these conditions can be easily distinguished on biopsy because Zoon's balanitis has characteristic diamond, or 'lozenge-shaped', keratinocytes and a lack of significant epithelial atypia. Both may have plasma cell-rich dermal infiltrates.

Figure 31.24 Erythroplasia of Queyrat. There is full-thickness epithelial atypia, with few multinucleate or dyskeratotic cells. The inflammatory infiltrate contains plasma cells. (H&E)

INTRAEPIDERMAL EPITHELIOMA (JADASSOHN)

The intraepidermal epithelioma (Jadassohn) has been regarded by some as a distinct clinicopathological entity, characterized by the presence of nests of atypical keratinocytes within the epidermis and having the potential to progress to invasive squamous cell carcinoma in a small number of cases.⁷⁷⁹⁻⁷⁸¹ As defined, it presents as a scaly plaque, usually on the lower part of the trunk, the buttocks, or the thighs, measuring 0.5–10 cm in diameter.⁷⁸⁰

Most authors do not recognize the existence of such an entity, which they believe is simply an expression of the Borst-Jadassohn phenomenon, a term used to describe the presence of sharply defined nests of morphologically different cells within the epidermis.^{782,783} This phenomenon may be seen in seborrheic keratoses (clonal variant), hydroacanthoma simplex, and some cases of Bowen's disease, actinic keratosis, and, rarely, epidermal nevi.^{784,785} It has also been seen in a tumor in which the nests of cells exhibited markers for hair follicle cells by immunoperoxidase: accordingly, that lesion was called an **intraepidermal pilar epithelioma**.⁷⁸⁶

MALIGNANT TUMORS

This group, which includes basal cell and squamous cell carcinomas, accounts for approximately 90% or more of all skin malignancies. These tumors constitute an important public health problem,⁷⁸⁷⁻⁷⁸⁹ despite their comparatively low mortality rate.⁷⁹⁰⁻⁷⁹² The lifetime risk for the development of skin cancer in the United States is 1 in 5.⁷⁹³ It was estimated that more than 2 million cases of non-melanoma skin cancer (NMSC) were diagnosed in the United States in 2004.⁷⁹⁴ In Germany between 1998 and 2001, the age-standardized rate for all NMSCs was 100.2 per 100,000 inhabitants per year for men and 72.6 for women, with 80% of all tumors being basal cell carcinoma.⁷⁹⁵ In Australia, it was estimated that in 2002, there were 374,000 new cases of basal cell carcinoma and squamous cell carcinoma.⁷⁹⁶ In most instances, the histopathological diagnosis is straightforward, but occasionally tumors are encountered that are difficult to classify because of some apparent morphological overlap with various appendageal tumors or because the tumor exhibits both basaloid and squamous differentiation. In these circumstances, immunohistochemistry may be of assistance.⁷⁹⁷

In a review of lethal non-melanoma skin cancers in Western Australia, 120 cases were recorded during a 5-year period. Of these cases, 89 were caused by squamous cell carcinoma, 22 by Merkel cell carcinoma, and 4 were adenosquamous carcinomas.⁷⁹⁸ The mortality increases sharply with age.⁷⁹⁹ A similar study in Danish patients found markedly different mortality rates between squamous cell carcinomas and basal cell carcinomas (in which it was very low).⁸⁰⁰

BASAL CELL CARCINOMA

Basal cell (trichoblastic) carcinomas are the most common cutaneous tumors, accounting for approximately 70% of all malignant diseases of the skin.⁸⁰¹ They exceed squamous cell carcinomas in frequency by a factor of approximately 5 : 1, although this ratio varies from 2 : 1 to 7 : 1 in different latitudes.⁸⁰²⁻⁸⁰⁶ The age-adjusted incidence per 100,000 varies from 106 in Canada to 980 in non-Hispanic white persons in southeastern Arizona to 1193 in Townsville, North Queensland, Australia.^{807,808} The incidence in northern Europe is lower than that in Canada.⁸⁰⁹ Of course, if solar keratoses are regarded as squamous cell carcinomas (see p. 816), then squamous cell carcinoma becomes more common than basal cell carcinoma.^{810,811} The overall incidence of basal cell carcinomas appears to be increasing,⁸¹² particularly in males older

than the age of 70 years.⁸¹³ There is evidence of a reduction in incidence in younger birth cohorts.⁷⁹⁵

Nomenclature

Because of the undoubted links between basal cell carcinoma and a follicular origin, there have been calls for it to be renamed trichoblastic carcinoma⁸¹⁴ and inferences that it should not be included as a tumor of the epidermis.⁸¹⁵ Major name changes for extremely common conditions are not well accepted by the general readership or the medical profession. While acknowledging the evidence of follicular differentiation and follicular markers in basal cell carcinomas, the author does not propose changing the title or textual location of this entity. Changes of this magnitude need to be evolutionary rather than confronting.

Clinical aspects

Basal cell carcinomas are found predominantly on areas of skin exposed to the sun, particularly in fair-skinned individuals.^{816–819} They are rare in darker-skinned people.^{820–823} Up to 80% of all lesions are found on the head and neck,^{802,824,825} whereas approximately 15% develop on the shoulders, back, or chest.⁸²⁶ There are isolated reports documenting involvement of the lacrimal caruncle,⁸²⁷ vermilion lip,⁸²⁸ breast,^{830,831} nipple,^{832,833} axilla,^{834–837} perianal region,^{837–842} vulva,^{837,843–845} penis,^{837,843–845} scrotum,^{837,846–850} inguinal region,⁸⁵¹ subungual skin and nail unit,^{852–856} lower part of the legs,⁸⁵⁷ and the palms^{851,858,859} and soles.^{860–862} Other unusual sites of involvement include pilonidal sinuses,⁸⁶³ venous ulcers,^{864,865} sternotomy scars,⁸⁶⁶ an acupuncture site,⁸⁶⁷ the skin overlying arteriovenous malformations,^{868,869} the nose affected by rhinophyma,^{870,871} and the scars that follow thermal burns,⁸⁷² radiation,^{873–875} chickenpox,⁸⁷⁶ leishmaniasis,^{877,878} smallpox,⁸⁷⁹ influenza,⁸⁸⁰ and BCG vaccination.^{881,882} Basal cell carcinomas develop in approximately 20% of organoid nevi,^{883–885} and, rarely, in epidermal nevi,^{24,886} fibroepithelial polyps,⁸⁸⁷ multiple trichoepitheliomas,⁸⁸⁸ epidermal cysts,⁸⁸⁹ ‘port wine’ stains,^{890–893} and solar lentigines.⁸⁹⁴ A basal cell carcinoma has been reported in association with granulocytic sarcoma of the skin.⁸⁹⁵ Multiple basal cell carcinomas may develop in the basal cell nevus syndrome (see p. 814) and in the rare Bazex’s syndrome (Bazex–Dupré–Christol syndrome; OMIM 301845), in which there is also follicular atrophoderma and hypohidrosis.^{896–899} It maps to Xq24–q27. They also occur in ROMBO syndrome (OMIM 180730), which includes vermiculate atrophoderma.⁹⁰⁰ Multiple basal cell carcinomas have also been reported in the cartilage hair hypoplasia (McKusick) syndrome (OMIM 250250) due to a mutation in the *RMRP* gene.⁹⁰¹ Furthermore, any patient who has had one basal cell carcinoma has a high probability of subsequently developing a further lesion.^{902,903} Patients with truncal lesions and those presenting with tumor clusters represent a high susceptibility group for the development of further lesions.^{794,904–907} Tumors in this site are commonly of the (multifocal) superficial type with a male predominance.⁹⁰⁸ There appears to be no risk for the development of noncutaneous cancers.⁹⁰⁹ It appears that different mechanisms determine the development of truncal and nontruncal basal cell carcinomas.⁹¹⁰ On the other hand, patients with lesions of the nasolabial fold seem to present with shorter evolution time from first symptom, have a smaller size, have less aggressive histological features, but require more complex reconstructions to remove them.⁹¹¹

Basal cell carcinomas are more common in males, presumably related to occupational and recreational exposure to UV light. They tend to occur in older people, although they have also been documented in children^{912–915} and young adults.⁹¹⁶ In children, there is often a clinical association with the basal cell nevus syndrome, Bazex’s syndrome, xeroderma pigmentosum, or an organoid nevus.⁹¹²

The clinical presentation of a basal cell carcinoma can be quite variable. It may be a papulonodular lesion with a pearly translucent edge, an ulcerated destructive lesion (‘rodent ulcer’), a pale plaque with variable induration, an erythematous plaque with visible telangiectasia,

or a partly cystic nodule.^{917,918} Lesions presenting as a large pore may show follicular differentiation microscopically.^{919,920} Giant lesions up to 20 cm in diameter,^{921–925} and variants with mutilation of the face have also been documented.^{926,927} Rare linear and polypoid forms have been reported.^{928,929} Approximately 2–5% of lesions are pigmented; basal cell carcinomas in black people and in the Japanese are often pigmented.^{822,930,931} Rarely, these pigmented variants mimic a malignant melanoma⁹³² or develop a depigmented halo.⁹³³ The confocal microscopy of pigmented basal cell carcinomas is distinctive.^{934–936} Dendritic melanocytes can be easily detected by this technique.⁹³⁷ It is also a highly sensitive method of diagnosing basal cell carcinomas of all types.^{938–940} Despite the marked variability in their appearance, the accuracy rate in the clinical diagnosis of basal cell carcinomas is still 60–70%.^{941,942}

Although most basal cell carcinomas are slow-growing, relatively nonaggressive tumors that are cured by most methods of treatment, a minority have an aggressive behavior with local tissue destruction and, rarely, metastasis.⁹⁴³ Aggressive subtypes have been linked with chronic sun exposure.⁹⁴⁴ These aspects are considered in further detail after the histopathology has been discussed.

Etiology

Although the prime etiological factor in the development of basal cell carcinoma is exposure to UV light, particularly the UVB wavelengths, solar dosimetry studies show a poor correlation between tumor density and UV dose.^{945–947} Indeed, susceptibility to UVB-induced inhibition of contact hypersensitivity appears to be a better indicator of cancer risk than cumulative sun exposure, suggesting an important role for immune surveillance in protecting against the development of basal cell carcinoma.⁹⁴⁸ A detailed review of the literature with meta-analysis and sensitivity analysis showed that outdoor workers are at significantly increased risk for developing basal cell carcinoma, with an inverse relationship between occupational UV exposure and basal cell carcinoma risk with latitude.⁹⁴⁹ Parenthetically, the sun-protection message may be ‘getting through’ to some members of the community. There are now calls for the use of supplemental vitamin D to counteract declining levels of this vitamin in sun-protected individuals.⁹⁵⁰ Tumor necrosis factor (TNF) may be an important mediator of the immunosuppression produced by UVB.⁹⁴⁸ Various mediators of UVB-induced damage are now being reported.^{951,952} Recreational sunlight exposure in adolescence and childhood appears to be a risk factor for the development of basal cell carcinoma.^{953–956} Tanning bed exposure may also be a contributory factor.⁹⁵⁷ Basal cell carcinomas of the trunk are related to the number of reported sunburns earlier in life.⁹⁵⁸ Intermittent exposure may be more important than chronic exposure because clinical actinic elastosis appears to be protective against sporadic lesions.⁹⁵⁹ UVB radiation produces DNA damage at mutation hot spots on the p53 tumor suppressor gene. Approximately 50% of all basal cell carcinomas studied have mutations of this gene.^{960,961} Telomerase activation appears to be important in the pathogenesis of basal cell carcinomas.⁹⁶² Whereas squamous cell carcinomas tend to develop at the sites of direct exposure to sunlight (dorsum of hands, ears, bald scalp, and lower lip), basal cell carcinomas are more common in sites slightly removed from this, such as the paranasal region and inner canthus.⁹⁶³ Other predisposing factors include radiotherapy,^{964–969} exposure to tar and asphalt,⁹⁷⁰ arsenical intoxication,^{583,971} adjuvant treatment of melanoma with isolated limb perfusion,⁹⁷² HPV infection,^{924,973} welding,⁹⁷⁴ and stasis dermatitis of the legs.^{975–977} There is no association with diet,⁹⁷⁸ but an inverse association between tea consumption and skin carcinogenesis was found in one study.⁹⁷⁹ In females, the risk of developing a basal cell carcinoma increases with the increasing number of nevocellular nevi.⁹⁸⁰ Smoking appears to be a risk factor in females for contracting basal cell carcinoma.⁹⁵⁷ This is based in part on a study of twin pairs discordant for cutaneous tumors.⁹⁸¹ It has been suggested

that smoking may play a role in inducing sclerosing variants.⁹⁸² Tumors have also developed following PUVA therapy in patients with psoriasis.⁹⁸³ UVA radiation, given to healthy volunteers, has produced decreased epidermal antigen-presenting cell activity that can be blocked by sunscreens.⁹⁸⁴ Accordingly, it seems that UVA may contribute to UV-induced immunosuppression.⁹⁸⁴

Basal cell carcinomas and squamous cell carcinomas occur in renal transplant recipients^{985–988} and in other circumstances of immunosuppression, such as malignant lymphoma or leukemia^{989–992} and the AIDS-related complex.^{993–996} In organ transplant recipients, the estimated incidence of non-melanoma skin cancer at 20 years after transplantation is 40–75%.⁹⁹⁷ The most critical risk factor is excessive UV radiation, particularly UVB irradiation. HPV and genetic factors also play a role.⁹⁹⁸ Tumors are more aggressive, commence at a younger age, and are more numerous in these circumstances. Squamous cell carcinomas are increased more than basal cell carcinomas, but the ratio of the two tumors still favors basal cell carcinoma.⁹⁹⁹ This is contrary to other reports that have found a reversal of the ratio and a squamous cell carcinoma:basal cell carcinoma ratio of 3:1.^{1000,1001} Basal cell carcinomas in solid organ transplant recipients tend to be more frequent in extracephalic sites and to be superficial in type.¹⁰⁰² They are strongly associated with sun exposure during childhood.¹⁰⁰³

Basal cell carcinomas are also aggressive in albinos.^{1004,1005} Basal cell carcinomas are now being seen after prolonged hydroxyurea therapy used in the treatment of myeloproliferative disorders.¹⁰⁰⁶

Genetic aspects

There is increasing evidence that genetic factors play a role in the susceptibility of some individuals to basal cell carcinoma.⁹⁴⁷ Mutations in the patched homologue 1 gene (*PTCH1*), which is known to be responsible for the nevoid basal cell carcinoma syndrome (see later), have also been reported in sporadic cases of basal cell carcinoma.^{1007–1011} *PTCH1* mutations have been found in 30–40% of sporadic basal cell carcinomas.¹⁰¹² Mutations in the *PTCH1* gene, the receptor of the sonic hedgehog, have downstream effects leading to the accumulation of the transcription factor Gli-1, which may play a role in the development of basal cell carcinomas.^{1013–1016} SOX9, a downstream target of the sonic hedgehog pathway, is expressed in all basal cell carcinomas as well as in adnexal neoplasms of the skin.¹⁰¹⁷ It is absent in Bowen's disease and Merkel cell carcinoma. This suggests a possible contribution of SOX9 to the pathogenesis of basal cell carcinomas. Mutations in other genes in the sonic hedgehog pathway have also been found in sporadic tumors.^{1018,1019} *BMI-1*, a gene belonging to the polycomb group of epigenetic gene silencers and which is upregulated by genes in the sonic hedgehog pathway, is overexpressed in basal cell carcinomas.¹⁰²⁰ Other unrelated genes have also been implicated.^{1021–1023} Various chemokines may contribute to tumor progression.¹⁰²⁴ There is also an association with HLA-DR7 and HLA-DR4 in some populations.^{1025,1026} Mutations in the *BAX* gene (bcl-2 associated X protein) and *P53* gene have also been found in sporadic cases.^{1027–1029} There is no association between a common polymorphism in the *MDM2* gene, a negative regulator of the p53 tumor suppressor, and basal cell carcinoma.^{1030–1032} Loss of heterozygosity on chromosome 4q32–q35 has also been reported in sporadic cases, implicating the *p33ING2/ING1L* and *SAP30* genes.¹⁰³³

Cell of origin

Basal cell carcinomas usually arise from the lowermost layers of the epidermis, although a small percentage may originate from the outer root sheath of the pilosebaceous unit.^{945,1034} Whatever their origin – lower epidermis or follicle – the cells in the basal cell carcinoma have many features in common with follicular epithelium, particularly follicular matrix cells, rather than follicular bulge cells as once

thought.¹⁰³⁵ There is a virtually identical cytokeratin pattern in basal cell carcinomas, trichoblastomas, and developing fetal hair follicles – compelling evidence for a common histogenetic pathway.^{1036,1037} Another study found a common expression pattern for epithelial cell adhesion molecule in basal cell carcinoma, early follicular embryogenesis, secondary hair germ, and the outer root sheath of the vellus hair follicle.⁸¹⁵ As previously stated, Ackerman now classifies basal cell carcinomas as trichoblastic carcinomas.⁸¹⁴ Further circumstantial evidence of this shared antigenicity is the finding of T lymphocytes in the upper portion of hair follicles, adjacent to a regressing basal cell carcinoma.¹⁰³⁸ In contrast to squamous cell carcinomas, basal cell carcinomas are difficult to produce experimentally in animals, although they have been produced in rats using chemical carcinogens.¹⁰³⁹ Human lesions, however, can be transplanted to nude mice, but only if the animals are athymic and lacking in natural killer cell activity.^{993,1040} Basal cell carcinomas are stroma dependent, and autotransplantation is unsuccessful if the stroma is not included.¹⁰⁴¹ This stromal dependency is the most likely reason for the low incidence of metastasis of these tumors.⁹⁴⁵ Fibroblasts in basal cell carcinomas differ from normal fibroblasts in several ways; they appear to have a regulatory role in the biology of basal cell carcinoma.¹⁰⁴²

An update of the previous guidelines for the management of basal cell carcinoma, produced by the British Association of Dermatologists, was published in 2008.¹⁰⁴³ Surgical excision is the preferred method of treatment for basal cell carcinoma. Mohs surgery is the treatment of choice for primary facial basal cell carcinomas with aggressive histopathology and for recurrent tumors on the face.¹⁰⁴⁴ It is also effective for basosquamous carcinoma, with a 5-year recurrence rate of 4.1% in one series.¹⁰⁴⁵ Curettage and cautery (electrodesiccation) is a good treatment for low-risk basal cell carcinomas.¹⁰⁴³ Other treatments include cryosurgery,¹⁰⁴³ photodynamic therapy,^{1043,1046–1048} topical imiquimod, and radiation therapy alone or in combination with surgery, particularly in treating basal cell carcinomas with perineural invasion.¹⁰⁴⁹ Palliative therapy with the epidermal growth factor receptor antagonist cetuximab¹⁰⁵⁰ and interferon- α -2b have also been used.¹⁰⁵¹ In patients who are immunosuppressed, withdrawal of this therapy has resulted in regression of basal cell carcinomas.¹⁰⁵² Reduction in immunotherapy can also be used in patients with multiple or aggressive tumors.

A review of the risk factors, epidemiology, genetics, and treatment options for basal cell carcinoma was published in 2011.¹⁰⁵³

Histopathology¹⁰⁵⁴

The reporting of basal cell carcinomas has now become more 'sophisticated' with various bodies producing minimum data sets. They were preceded by publications stressing the importance of the histological pattern.^{1055,1056} The minimum data set produced by the Royal College of Pathologists requires, in essence, the histological type (growth pattern), type of differentiation (the presence of a squamous component), the presence of perineural invasion, and the distance to the nearest peripheral margin and to the deep margin.¹⁰⁵⁷ Minimum data sets requiring clearances are controversial, particularly when there is no worldwide consensus on how to respond to the information.

There is considerable variability in the morphology of basal cell carcinomas, and as a consequence, a number of histopathological subtypes have been defined. Certain features are shared by more than one of these subtypes, and these aspects are considered first.

Basal cell carcinomas are composed of islands or nests of basaloid cells, with palisading of the cells at the periphery and a haphazard arrangement of those cells in the centers of the islands. The tumor cells have a hyperchromatic nucleus with relatively little, poorly defined cytoplasm. The intercellular bridges are invisible on routine light microscopy. There are numerous mitotic figures, sometimes atypical,¹⁰⁵⁸ and a correspondingly high number of apoptotic tumor cells.¹⁰⁵⁹

This high rate of cell death accounts for the paradoxically slow growth of basal cell carcinomas that possess numerous mitoses.¹⁰⁶⁰

The vast majority of cases show some attachment to the undersurface of the epidermis. Ulceration is not infrequent in larger lesions. Lesions of long standing and aggressive tumors usually extend into the lower dermis. Deep extension occurs either diffusely or within the paths of the cutaneous adnexae.¹⁰⁶¹ Involvement of the subcutis or of the underlying cartilage in lesions of the nose and ear is quite uncommon.¹⁰⁶² Perineural invasion is present in nearly 1% of cases, although the incidence is higher in aggressive variants.^{1063–1065} In one series, perineural invasion was present in 2.74% of patients treated with Mohs surgery.¹⁰⁶⁶ It was most often seen in infiltrating, morpheic, and basosquamous types, particularly on the face.¹⁰⁶⁶

Islands of tumor cells are surrounded by a stroma, which is newly formed and different from the adjacent dermis. Clefting at the stromal–tumor interface is common.¹⁰⁶⁷ This stroma contains variable amounts of acid mucopolysaccharides. Laminin and types IV, V, and VII collagen are present in the basement membrane, which separates the tumor cells from the stroma.^{1068,1069} However, there is decreased expression of some other basement membrane components, which may facilitate their ability to invade (discussed previously).^{1070,1071} The expression of MMPs may also enhance this ability to invade.¹⁰⁷² Aggressive basal cell carcinomas show discontinuous staining for laminin and type IV collagen but a marked stromal myofibroblastic response with an increase in stromal fibronectin.^{1071,1073} They are also more likely to express p53 protein.¹⁰⁷⁴ Angiogenesis is also present in the stroma.¹⁰⁷⁵ Amyloid, which is formed by the tumor cells, is present in the stroma in up to 50% of cases.^{1076–1078} It is less common in aggressive variants.¹⁰⁷⁷ Amyloid may lead to apparent lack of sensitivity to radiotherapy.¹⁰⁷⁹ The adjacent dermis shows solar elastosis in more than 90% of cases, although its degree is sometimes mild.¹⁰⁸⁰ The overlying epidermis may show the changes of a solar keratosis, although this is only rarely the precursor of a basal cell carcinoma.¹⁰⁸¹

A variable inflammatory cell infiltrate is usually present, although there is a paucity of cells in some recurrences. The presence of plasma cells in the infiltrate correlates with ulceration. The infiltrate is usually composed mainly of T cells, the majority of which are CD4⁺.^{1082–1084} Natural killer cells, mast cells,¹⁰⁸⁵ and Langerhans cells are also present.^{1082,1086–1088} Cell-mediated immunity appears to play a role in the focal regression seen in up to 20% of tumors.^{1083,1089} The expression of interleukin-2 receptor (IL-2R) is increased in regressing lesions.¹⁰⁸³ Active regression is characterized by the presence of a lymphocytic infiltrate that surrounds and penetrates tumor nests, with disruption of the normal palisaded outline and the formation of numerous apoptotic tumor cells.^{1086,1089} Both C4⁺ and CD8⁺ cells are present in regressing lesions.¹⁰⁹⁰ Past regression can be recognized by finding areas of eosinophilic new collagen within a tumor, associated with the absence of tumor nests, an increase in small blood vessels, loss of appendages, and a variable inflammatory cell infiltrate.¹⁰⁸⁹ Prominent central regression with the formation of scar tissue is a feature of the so-called ‘field fire’ type of basal cell carcinoma.

Calcification may be present in the center of the keratin cysts that form in several of the histological subtypes. Ossification is an exceedingly rare event.^{1091–1094} Another rare finding is the presence of transepidermal elimination of tumor nests.¹⁰⁹⁵ Also rare is the development of pseudoepitheliomatous hyperplasia or keratoacanthoma-like changes in the epidermis following irradiation or excision of a basal cell carcinoma:¹⁰⁹⁶ this is known as pseudorecivism.¹⁰⁹⁷

Basal cell carcinomas or closely related changes may overlie a dermatofibroma.¹⁰⁹⁸ This is discussed on page 994. Similar basaloid proliferations may overlie a cutaneous myxoma¹⁰⁹⁹ and connective tissue/mesenchymal hamartomas.¹¹⁰⁰ Basal cell carcinomas have also been reported in association with seborrheic keratoses, intradermal nevi,¹¹⁰¹ porokeratosis, Darier’s disease, lupus vulgaris, keratoacanthoma, desmoplastic tricholemmoma,¹¹⁰² neurofibromas, and, as previously

mentioned, organoid nevi¹¹⁰³ and trichoepitheliomas.⁸⁸⁸ Combined (intermingled) basal cell carcinoma and malignant melanoma are rare.¹¹⁰⁴

Sometimes no tumor can be found in a biopsy specimen despite a strong clinical suspicion that basal cell carcinoma is present. This is particularly so with the (multifocal) superficial basal cell carcinoma where nests can be widely spaced or undergo regression. It is good practice to order, routinely, three levels of all punch and shave biopsies to prevent sampling errors. Further levels may be required. Clues in an initial nondiagnostic slide that suggest that deeper sections may yield basal cell carcinoma include focal basal atypia, stromal or superficial fibrosis, empty dermal spaces, equivocal adnexae, and microcalcifications.¹¹⁰⁵

The tumor cells in basal cell carcinoma resemble epidermal basal cells in their glycoconjugate pattern, their keratin expression,^{1106,1107} and the presence of bcl-2.^{1108–1112} They differ by the absence of CD95 (APO-1/FAS), which is present in epidermal keratinocytes, particularly in sun-exposed skin.¹¹¹³ Actin, a microfilament that contributes to cell motility and invasiveness of cancer cells, is often present in the nodular component of mixed nodular and infiltrating types but much less often in pure nodular lesions.¹¹¹⁴ The expression of p53 is related to aggressive variants of basal cell carcinoma.¹¹¹⁵ The vast majority of basal cell carcinomas express CD10.¹¹¹⁶ The smaller the number of positive tumor cells, the larger the number of positive stromal cells, particularly in sclerosing variants.¹¹¹⁶ Only stromal cells express CD10 in squamous cell carcinomas.^{1116,1117} Clinically aggressive basal cell carcinomas have low labeling with bcl-2.^{1118,1119} The cells also express cytokeratins, which are found only in follicular epithelium.^{1106,1120} CAM5.2 (CK8, CK18, and CK19) may be useful in the distinction of basal cell carcinoma from sebaceoma. It is usually negative in sebaceoma and squamous cell carcinoma and positive in a proportion of basal cell carcinomas and trichoepitheliomas.¹¹²¹ In one study, all basal cell carcinomas expressed CK5 and CK17, more than half expressed CK7, and most were negative for CK14.¹¹²² Basal cell carcinomas express p63, but not usually as strongly as squamous cell carcinomas.¹¹²³

Various morphological subtypes have been defined, including nodular (solid), micronodular, cystic, superficial (superficial multifocal), pigmented, adenoid, infiltrating, sclerosing, keratotic, infundibulocystic, metatypical, basosquamous, and fibroepitheliomatous.¹¹²⁴ Mixed patterns are quite common (Fig. 31.25).¹⁰⁵⁵ Carlson and colleagues presented evidence that a histological continuum exists that moves from low-risk types (superficial and nodular) via less frequent transitional, mixed types toward the high-risk micronodular, morpheic, and infiltrating types.¹¹²⁵ The host immune response and stromal alterations accompany this progression. Several other rare variants have also been described. It should be remembered that punch and shave biopsy techniques provide approximately 80% accuracy in the diagnosis of the various subtypes of basal cell carcinoma.¹¹²⁶

Nodular (solid) type

The nodular variant, also known as the large nest type, accounts for approximately 70% of all cases. It is composed of islands of cells with peripheral palisading and a haphazard arrangement of the more central cells. An unusual variant featuring centrally palisaded cells that form Verocay-like bodies has been reported.¹¹²⁷ Retraction spaces sometimes form between the tumor islands and the surrounding stroma. Ulceration may be present in larger lesions. The author uses the term ‘solid’ rather than nodular because of the frequent use of the term ‘nodular’ to describe a clinical variant of basal cell carcinoma that is not always of this histological subtype.

Micronodular type

The micronodular variant resembles the solid type, but the nests are much smaller and the peripheral palisading is not always as well developed (Fig. 31.26). The micronodular type has a much greater

Figure 31.25 Basal cell carcinoma of mixed type with (A) a superficial solid and micronodular component and (B) a deep sclerosing/morpheic area. This lesion had not been treated previously, supporting the view that aggressive lesions may develop *de novo*, without previous treatment. (H&E)

propensity for local recurrence than the solid type.¹¹²⁸ It usually has little or no fibro-inflammatory response,¹¹²⁵ but clinically it may mimic a sclerosing variant. Sometimes it infiltrates quite widely through the dermis and extends into the subcutis. The micronodular type is often included incorrectly with the infiltrating or nodular (solid) types.

Cystic type

One or more cystic spaces are present toward the center of some or all of the tumor islands.⁹¹⁷ This results from the degeneration of tumor

Figure 31.26 Basal cell carcinoma. The superficial part is of solid type, and the deeper nests are of micronodular type. (H&E)

cells centrally, and it may be associated with increased mucin between the tumor cells adjacent to the cyst. Rarely, a cystic basal cell carcinoma can mimic a hidrocystoma on a superficial biopsy.¹¹²⁹

Superficial (multifocal) type

A three-dimensional reconstruction study has shown that the apparently discrete nests of tumor cells are interconnected, suggesting a unicentric origin.¹¹³⁰ The author has stubbornly continued to include the word ‘multifocal’ in the title because of the wide separation of the nests in some lesions. However, the finding that the tumor is monoclonal makes it unlikely that the lesion is other than unifocal in its origin (Fig. 31.27).¹¹³¹ The superficial basal cell carcinoma is composed of multiple small islands of basaloid cells attached to the undersurface of the epidermis and usually confined to the papillary dermis. Acantholysis has been reported in a few cases.¹¹³² A narrow zone of fibrous stroma may surround the nests. There is usually a patchy band-like lymphocytic infiltrate and an increase in thin-walled vessels.¹¹³³ This pattern accounts for 10–15% of all tumors and is the usual pattern seen in lesions removed from the shoulder region.⁸⁴⁶ The age of patients with this subtype is lower than that for other types.¹¹³⁴ A recent study found a more equal distribution of superficial variants on the face, trunk, and limbs, tending to blur the difference between intermittent and continuous sun exposure as the causative environmental agent.⁷⁹⁵

Pigmented type

Melanin pigment is usually formed in solid, micronodular, multifocal superficial, or follicular variants.¹¹³⁵ Functional melanocytes are

Figure 31.27 Basal cell carcinoma of (multifocal) superficial type. (H&E)

scattered through the tumor islands, and there are numerous melanophages in the stroma.¹¹³⁶ There are few melanosomes within the tumor cells. Melanosome complexes form in tumor cells as a consequence of repeated cycles of phagocytosis of melanosome-containing tumor cells that have undergone apoptosis.¹¹³⁷ Basal cell carcinomas of the usual type are also populated by some melanocytes.¹¹³⁸ Other pigmented phenomena in basal cell carcinomas are the colonization of one by a melanoma *in situ*, the metastasis of a melanoma to one, and the presence of a combined melanoma and basal cell carcinoma.^{1139–1141}

Dermoscopic findings and their histopathologic correlates in pigmented basal cell carcinoma include wheel-shaped structures with radial extensions (tumor nests with finger-like extensions to the epidermis and central pigmentation), blue-gray ovoid structures (tumor nests with pigment aggregates and peripheral buds), blue-gray globules (rounded tumor nests in papillary dermis), brown dots (pigment deposits at the dermal–epidermal junction), and a blue-white veil above brown pigmented areas (orthokeratotic epidermis with pigment accumulation beneath).¹¹⁴² The cytology of these tumors includes cohesive sheets, branching fragments, and club-shaped groups of small basaloid cells with peripheral palisading and pigment deposits both within and outside the epithelial fragments.¹¹⁴³

Adenoid type

The adenoid variant consists of thin strands of basaloid cells in a reticulate pattern. Stromal mucin is often quite prominent. The adenoid type is quite uncommon in a pure form. It may occur in association with the solid type. The rare trabecular variant has some adenoid features.¹¹⁴⁴

Infiltrating type

This nonsclerosing variant has an infiltrative rather than an expansile pattern of growth.¹¹⁴⁵ It accounts for approximately 5% of all tumors, although this figure is higher in some patient groups.¹¹⁴⁶ The histological features are distinctive, with elongated strands of basaloid cells, four to eight cells thick, infiltrating between collagen bundles (Fig. 31.28).¹¹⁴⁵ Sometimes, even narrower strands are present, with spiking projections.¹¹⁴⁵ There may be a slight increase in fibroblasts, but there is no significant fibrosis. Often, there is a solid pattern superficially with the infiltrating nests at the periphery or base of the lesion. Sometimes a focal infiltrative pattern is seen in the re-excision specimen of a biopsy-proven solid (nodular) basal cell carcinoma.¹¹⁴⁷ These changes are limited to the region of the biopsy scar and appear to represent a scar-induced phenomenon without any sinister connotations. Like the sclerosing variant, it has a clinically indistinct border, but it differs from that variant in its opaque, yellow-white color.¹¹⁴⁵ Metallothionein, a

Figure 31.28 (A) Basal cell carcinoma of infiltrating type, with (B) elongated nests of basaloid cells infiltrating between the collagen bundles of the dermis. (H&E)

presumptive marker of aggressive clinical behavior, is increased in the infiltrative variant.¹¹⁴⁸

Sclerosing type

The sclerosing category includes lesions that have also been referred to as fibrosing, scirrhous, desmoplastic, and morpheic.^{1149,1150} The uncommon ‘field fire’ type with central fibrosis resulting from regression should not be included in this category. Up to 5% of all basal cell carcinomas are of the sclerosing (morpheic) type.¹¹⁴⁹ The tumor presents as an indurated, pale plaque with a slightly shiny surface and clinically indistinct margins.¹¹⁴⁹ There are narrow elongated strands and small islands of tumor cells embedded in a dense fibrous stroma.¹¹⁵⁰ If the stroma has dense, eosinophilic areas resembling a keloid, then the term ‘morpheic’ has traditionally been used, although at other times this term has been used interchangeably with ‘sclerosing’. This was apparently the case in a series that found morpheic or partly morpheic features in 21.8% of all basal cell carcinomas.¹¹⁵¹ Apparent sclerosing features are not uncommon in superficial shaves of ulcerated basal cell carcinomas, but sclerosis is relatively uncommon in deeper portions of these tumors when they are subsequently excised. Truly morpheic lesions do not respond well to most standard therapies, other than surgery.¹¹⁵¹ The term ‘keloidal’ has been applied to basal cell carcinomas with thick sclerotic keloidal collagen bundles in the stroma.^{1152–1156} A selectively enhanced procollagen gene expression has been found in the sclerosing variant.¹¹⁵⁷ Also, large defects have been found in the

Figure 31.29 Basal cell carcinoma of infundibulocystic type. (H&E)

basal lamina that surrounds the tumor nests.¹¹⁵⁸ Smooth muscle α -actin and myosin are often present in the stroma.

Keratotic type

The keratotic variant is similar to the solid type, with nests and islands of basaloid cells with peripheral palisading.¹¹⁵⁹ It differs in the presence of squamous differentiation and keratinization in the centers of the islands.¹¹⁶⁰ There is usually very little stroma and no lobular arrangement or follicular differentiation.¹¹⁵⁹

Infundibulocystic type

The uncommon infundibulocystic variant, found most often on the face, is often confused with the keratotic type.^{1161–1165} It is small, well circumscribed, and composed of nests of cells arranged in an anastomosing manner with little stroma (Fig. 31.29). There are numerous small infundibular cyst-like structures containing keratinous material and sometimes melanin.¹¹⁶¹ The stroma may contain amyloid and/or melanin.¹¹⁶¹ Multiple lesions have been reported in a patient with HIV infection.¹¹⁶⁶ Hereditary cases (OMIM 604451) appear to form a distinctive genodermatosis that is different from the nevoid basal cell carcinoma syndrome.^{1167,1168} Genetic studies have mapped the defect to chromosome 9q22.3, flanking the *PTCH* gene.¹¹⁶⁷

Metatypical type

Although the term ‘metatypical’ is sometimes applied to tumors with mixed basaloid and squamous features, it should be reserved for the rare basal cell carcinoma composed of nests and strands of cells maturing into larger and paler cells (Fig. 31.30).^{1054,1160} Peripheral palisading is often lost. The cells express much less keratin 17 and keratin 8 than do the cells in the more usual types of basal cell carcinoma.¹¹⁶⁹ Peripheral palisading is less obvious than usual, and the stroma is often prominent. This variant is regarded by some as having metastatic potential.¹¹⁷⁰ Metatypical basal cell carcinomas seem to have declined somewhat in recent years. It may have something to do with the declining use of radiotherapy in the primary treatment of basal cell carcinomas. The metatypical areas were often in recurrent lesions.

Basosquamous carcinoma

Basosquamous carcinoma is a controversial entity that can be defined as a basal cell carcinoma differentiating into a squamous cell carcinoma.^{1160,1171–1173} It is composed of three types of cells: basaloid cells, which are slightly larger, paler, and more rounded than the cells of a solid basal cell carcinoma; squamoid cells with copious eosinophilic

Figure 31.30 Basal cell carcinoma of metatypical type. There are larger cells with loss of palisading. (H&E)

cytoplasm; and an intermediate cell that resembles that seen in metatypical tumors.^{1160,1173} Accordingly, the basosquamous carcinoma is sometimes confused with metatypical and keratotic basal cell carcinomas. It also needs to be distinguished from basaloid squamous cell carcinoma, which when present in non-genital and non-perianal areas has often arisen in overlying Bowenoid atypia. Basaloid squamous cell carcinomas are almost always EMA⁺/Ber-EP4⁻.¹¹⁷⁴ It is an aggressive infiltrative lesion with metastatic potential.^{1175,1176} Perineural invasion is present in up to 10% of cases.¹⁰⁴⁵ It may show extensive subclinical spread.¹¹⁷⁷ This tumor shows some areas of Ber-EP4 positivity, in contrast to squamous cell carcinoma, which is always negative.¹¹⁷⁸ Furthermore, the distribution of basosquamous carcinomas matches basal cell carcinomas more closely than squamous cell carcinomas.¹¹⁷⁹

With dermoscopy, basosquamous carcinomas have overlapping dermoscopic features of both basal cell carcinoma and squamous cell carcinoma. These include arborizing vessels, ulceration or blood crusts, blue-gray blotches, and/or pigmentation structures (features of basal cell carcinoma); and keratin masses, white structureless areas, surface scale, white ‘clods, circles, or lines’, blood spots in keratin masses, and/or dotted, linear, irregular, or hairpin vessels (features of squamous cell carcinoma).¹¹⁸⁰

Fibroepithelioma

Fibroepithelioma presents as a soft nodular lesion resembling a fibroma or papilloma, often on the lower part of the back.^{1181,1182} It is composed of thin anastomosing strands of basaloid cells set in a prominent loose stroma (Fig. 31.31).¹¹⁸³ The cells display a high proliferative index.¹¹⁸⁴ Symplastic-type epithelial giant cells were present in one case.¹¹⁸⁵ The stroma has no elastic tissue.¹¹⁸¹ Merkel cells are quite prominent – a feature of benign follicular tumors.¹¹⁸⁶ Pigmentation is rare.¹¹⁸⁷ It has been suggested, and subsequently disputed, that this variant derives its histological pattern from the spread of basal cell carcinoma down eccrine ducts, eventually replacing them with solid strands of tumor.^{860,1188,1189} A significant number of basal cell carcinomas on the sole have a fibroepithelioma-like growth pattern.¹¹⁹⁰ A further area of dispute involves the histogenesis of these tumors. Whereas Ackerman and Gottlieb regard them as variants of basal cell (trichoblastic) carcinoma, Bowen and LeBoit contend that they are fenestrated trichoblastomas.^{1191,1192} Androgen receptors were expressed in 10 of 13 cases in one series.¹¹⁹³ This variant can be diagnosed by its dermoscopy pattern.¹¹⁹⁴ A rare cystic variant of fibroepithelioma has been reported.¹¹⁹⁵

Figure 31.31 Fibroepithelioma variant of basal cell carcinoma, with thin cords of cells set in a fibrous stroma. (H&E)

Confocal microscopy at the level of the dermal–epidermal junction shows ‘holes’ corresponding to the loose stroma, outlined by tumor cords, as well as plump, bright cells that represent melanophages in pigmented lesions.¹¹⁹⁶

Miscellaneous variants

Appendageal differentiation is sometimes present in basal cell carcinomas.¹¹⁹⁷ Follicular (pilar) variants have already been mentioned. Matrical and trichilemmal differentiation may also occur:^{1198–1203} basal cell carcinomas that show matrical differentiation require differentiation from matrical carcinomas (see p. 922). The tumor cells express nuclear and membranous β -catenin and also osteopontin.^{1204,1205} β -Catenin, predominantly nuclear, is also seen in other variants, particularly the infiltrative and morpheic types.^{1206–1208} Sebaceous differentiation is sometimes seen in areas of an otherwise typical basal cell carcinoma: such lesions require differentiation from other sebaceous tumors (see p. 926). The vacuolated sebaceous cells express EMA, a feature not seen in the usual basal cell carcinoma.¹²⁰⁹ A rare variant with histochemical and ultrastructural features of apocrine differentiation has been reported.^{1144,1210} Tumors with eccrine differentiation also occur, and these shade into lesions best classified with eccrine carcinomas.^{1211,1212} (see p. 965).

Other variants include the exceedingly rare *granular cell*,^{1213–1216} *clear cell* (**Fig. 31.32**),^{1217–1222} and ‘*signet-ring*’ cell (hyaline inclusion) types.^{1223–1228} The clear cell variant appears to begin ultrastructurally as lysosomes, suggesting that it forms part of a spectrum with the granular cell variant.¹²²⁹ The granular cells sometimes express CD68.¹²¹⁵ They usually express Ber-EP4 and MNF116.¹²³⁰ Lesions with *giant tumor cells* and large nuclei have been variously reported as ‘basal cell epithelioma with giant tumor cells’, ‘basal cell carcinoma with monster cells’, and ‘pleomorphic basal cell carcinoma’.^{1231–1233} The giant cells are cycling, and they do not appear to represent a senescent change.¹²³⁴ There is one report of this variant in which there were stromal giant cells as well.¹²³⁵ *Adamantinoid*,¹²³⁶ *schwannoid*,^{1237,1238} *trabecular*,¹¹⁴⁴ and *neuroendocrine differentiation*^{1239–1242} are further variants. It has been suggested that the tumor reported as a basal cell carcinoma with thickened basement membrane was really a trichilemmal carcinoma.^{1243,1244} The rare lesion showing *myoepithelial differentiation* needs to be distinguished from a carcinosarcoma (see p. 824).¹²⁴⁵ A malignant melanoma metastatic to a basal cell carcinoma simulated the pattern of a basomelanocytic tumor.¹²⁴⁶

Figure 31.32 Basal cell carcinoma with solid (nodular) and clear cell areas. (H&E)

Electron microscopy

The tumor cells have a large nucleus and cytoplasm containing a few tonofilaments. There are a small number of desmosomes and some thin processes on the cell surface.¹²⁴⁷ The appearances resemble those of the primary epithelial germ.¹²⁴⁸ Stromal amyloid is sometimes present, and this appears to be formed in the cytoplasm of tumor cells. Myofibroblasts have been found in the stroma.¹²⁴⁹

Cytology

The cytological diagnosis of basal cell carcinoma is made by finding large clusters of cells with crowded nuclei.^{1250,1251} Peripheral palisading can seldom be appreciated in cytological preparations.¹²⁵⁰ It has high diagnostic accuracy, although its use is limited.¹²⁵²

Recurrences

The 5-year recurrence rate for basal cell carcinomas is approximately 5%, although this varies with the type of treatment.^{1253–1256} The figure rises to 9% with long-term follow-up.¹²⁵⁷ Although one study found almost no difference in the recurrence rate of completely excised tumors and those with tumor at one excision margin,¹²⁵⁸ this is contrary to most reports,^{1259,1260} which have found that the distance to the closest resection margin is an important predictor of recurrence.¹²⁶¹ In another report, the recurrence rate was noted to be 1.2% in cases of adequately excised lesions, 12% if tumor was present within one

high-power field of a margin, and 33% if tumor was present at the excision margin.¹²⁶² In another study, the 5-year recurrence rate was 26% when the margin was involved and 14% in cases with free margins.¹²⁶³ Residual tumor is found in only 60% of re-excision specimens following a report of tumor at an excision margin.¹²⁶⁴ Failure to find tumor in all such re-excisions may result from an insufficient amount of tumor surviving to be detected or because the residual cells spontaneously die or are destroyed by a local inflammatory reaction. Another possibility is that the incompleteness of the initial excision was more apparent than real. The presence of residual tumor is more likely when both lateral and deep margins were initially involved.¹²⁶⁵ Failure to detect tumor in re-excision specimens, combined with a recurrence rate thought to be 30–50%, has resulted in a view that additional resection is not always necessary when margins are positive.¹²⁶⁶ One study found that recurrence was unlikely in incompletely excised basal cell carcinomas of superficial or nodular types, less than 1 cm in diameter, located anywhere except the nose or ears, and with less than 4% marginal involvement.¹²⁶⁷ An accompanying comment suggested that re-excision should be carried out for incompletely excised lesions.¹²⁶⁸ However, if recurrence does occur, subsequent recurrences are sometimes difficult to control.^{1269,1270} Patients with small primary basal cell carcinomas that appear to have been completely removed after a biopsy procedure are at risk for recurrence without further treatment.¹²⁷¹

All these studies need to be reconsidered in the context of a more recent study published in 2005.¹²⁷² It concluded that serial transverse cross-sectioning (bread-loafing) at 4-mm intervals of elliptical excision specimens from facial basal cell carcinomas excised with 2-mm surgical margins is only 44% sensitive in detecting residual tumor at the surgical margin.¹²⁷² In other words, the pathology report would indicate negative margins in 56% of tumors in which the surgical margins are actually involved.¹²⁷²

Recurrences are more common in lesions on the nose, the nasolabial fold, and the inner canthus, but this may in part be related to a difficulty in achieving adequate margins in these sites.^{1259,1273,1274} Peri-orbital recurrences may be associated with orbitocranial invasion, but fortunately this is quite uncommon.¹²⁷⁵ Infiltrative, micronodular, and (multifocal) superficial types of basal cell carcinoma are more likely to recur than nodular types.^{1055,1261,1276–1278} Metatypical and sclerosing variants may also be associated with more aggressive behavior.^{1279–1281} Recurrences are also more likely in patients who have multiple skin cancers.^{1282,1283} It is now generally accepted that the majority of recurrent basal cell carcinomas are aggressive from the onset, and that in many cases this can be predicted from the histological appearances of the original tumor.^{1284,1285} Notwithstanding these studies, tumors recurring after previous radiotherapy are usually aggressive and infiltrative.¹²⁸⁶ It is unlikely that all such lesions were of an aggressive type initially. A review of the pertinent literature on this subject in 2004 concluded that both intrinsic biological factors and extrinsic management factors play a role in the development and progression of aggressive basal cell carcinomas.¹²⁸⁷ Note that some studies have shown no correlation between the histological type and the recurrence rate, although a lack of uniformity in the histological classification of basal cell carcinomas makes the comparison of some series almost meaningless.^{1258,1279} Basal cell carcinomas in young adults are not more aggressive than those occurring in older patients, as once thought.¹²⁸⁸

Numerous reports document changes in the cells and stroma of basal cell carcinoma, some of which appear to provide explanations for the aggressiveness or otherwise of particular variants of basal cell carcinoma.^{1289–1296} Tumors showing aneuploidy and hyperexpression of cyclin D1 are more likely to have an unfavorable outcome.¹²⁹⁷ Angiogenesis may be an important step in the acquisition of an aggressive phenotype.^{1298,1299} Acquisition of trisomy 6 by tumor cells may lead to the emergence of metastatic potential.¹³⁰⁰

Metastases

The usual criteria used for the acceptance of metastatic basal cell carcinoma are a previous or present primary lesion in the skin and a metastatic lesion that has a histological picture similar to that of the primary and that could not have arisen by direct extension from the primary lesion.¹³⁰¹ Metastases are rare, occurring in approximately 0.05% of cases.^{1301–1303} This low incidence is probably related to the stromal dependence of basal cell carcinomas, which presupposes that only large tumor emboli with attached stroma are successful in implanting.¹³⁰⁴ Accordingly, it is not surprising that lesions that give origin to metastases are large, ulcerated, and neglected.^{1305,1306} Neglected lesions may also directly infiltrate vital structures such as the brain.¹³⁰⁷ Metatypical features and/or squamous differentiation have also been regarded as important,^{1170,1175,1308} although these changes were present in only 15% of the primary lesions in one review of metastasizing basal cell carcinomas.¹³⁰¹ Lesions on the scrotum appear to have an increased risk of metastasis.¹³⁰⁹ In one small study, immunohistochemical markers for Ki-67, p53, and bcl-2 in the primary lesion did not distinguish between metastatic and non-metastatic tumors.¹³¹⁰ Ber-EP4 positivity of the metastatic deposits helps to distinguish such lesions from metastatic basaloid squamous cell carcinoma.¹³¹¹

Metastases occur most commonly in the regional lymph nodes.^{1312,1313} Metastatic basal cell carcinoma was diagnosed by sentinel lymph node biopsy in one case.¹³¹⁴ It was only carried out because lymphatic invasion was present in the primary cutaneous basal cell carcinoma.¹³¹⁴ Bones,¹³¹⁵ lungs,¹³¹⁶ and liver are less frequent sites of involvement.^{1306,1317} Other organs and the subcutis are rarely affected.¹¹⁷⁰ Aspiration metastasis to the lung has been recorded.¹³¹⁸ The median interval between the diagnosis of the primary lesion and signs of metastasis is approximately 9 years, whereas the interval between the appearance of the metastases and the death of the patient is approximately 1 year.¹³⁰¹ Long survivals have occasionally been reported.¹³¹⁹ Systemic amyloidosis^{1320,1321} and a myelophthisic anemia secondary to marrow infiltration¹³²² have been documented in patients with metastatic basal cell carcinomas.

Differential diagnosis

The differential diagnosis of basal cell carcinoma includes adnexal tumors with follicular, sebaceous, or sweat gland differentiation as well as certain types of squamous cell carcinoma. **Trichoepitheliomas** (including 'classic' or variant forms) usually exhibit a more organoid growth pattern than that of basal cell carcinoma, which is composed of cellular lobules of similar size. Broad connections to the epidermis are uncommon in dermal hair sheath tumors, including trichoepithelioma, but are regularly present in cases of basal cell carcinoma. Papillary mesenchymal bodies are common in trichoepithelioma but are only occasionally encountered in keratotic basal cell carcinomas. The fibrous matrix of trichoepithelioma has a different appearance from the fibromyxoid stroma of basal cell carcinoma, and stromal retraction is not a prominent feature of the former tumor. A band-like peritumorous reaction with peanut agglutinin has been reported in most basal cell carcinomas¹³²³ but not in trichoepitheliomas.¹³²⁴ Other features that can be used to distinguish these two tumors are the staining pattern for bcl-2 (expressed in virtually all cells in most basal cell carcinomas but only weakly in some aggressive variants and only in the basal layer of trichoepitheliomas) and CD34 (found in the peritumoral fibroblasts around trichoepitheliomas but not in those around sclerosing basal cell carcinomas).^{1324–1326} Another recent study showed that bcl-2 was not helpful in distinguishing nodular basal cell carcinoma from trichoepithelioma, in terms of either frequency or pattern of staining, but that the rate of CK15 staining was significantly higher among trichoepitheliomas than in basal cell carcinomas.¹³²⁷ Whereas most basal cell carcinomas show epithelial staining with CD10, trichoepitheliomas do not usually have epithelial expression alone, but they

usually show stromal expression of CD10. Similar results with CD10 can help distinguish basal cell carcinoma from trichoblastoma.¹³²⁸

The desmoplastic trichoepithelioma can most often be distinguished from morpheaform basal cell carcinoma in excisional biopsies because of striking differences in overall tumor image. Desmoplastic trichoepithelioma shows a plate-like, circumscribed configuration in the dermis that usually includes overlying epidermal hyperplasia, horn cysts, and blunt-ended narrow strands of basaloid cells with an absence of irregularly expansile cell nests. Desmoplastic trichoepithelioma also occurs in a somewhat younger patient population than is typical for morpheaform basal cell carcinoma (although there can be overlap), and unlike the latter lesion, it is positive for epithelial membrane antigen by immunohistochemistry. The MMP stromelysin 3 was found in the stromal cells surrounding islands of morpheaform basal cell carcinoma in 68% of cases but was negative in all examples of desmoplastic trichoepithelioma.¹³²⁹ Staining for fibroblast-activation protein, a membrane-bound glycoprotein expressed in granulation tissue and peritumoral stromal fibroblasts, may prove to be of value in this particular differential diagnostic problem. In one study, positive staining was observed in peritumoral stromal fibroblasts of all cases of infiltrative/morpheaform basal cell carcinoma and none of the cases of desmoplastic trichoepithelioma.¹³³⁰ Diffusely positive staining for p75 neurotrophin receptor is characteristic of desmoplastic trichoepithelioma, but unfortunately there is significant overlap of staining with infiltrative basal cell carcinoma (as well as microcystic adnexal carcinoma).¹³³¹ As noted previously, CK17 is an effective stain for basal cell carcinomas of a variety of types. A study by Anderson-Dockter *et al.* demonstrated that tumor islands of morpheaform basal cell carcinoma are CK17⁺, whereas those of desmoplastic trichoepithelioma are negative. This positive staining can also be exploited in determining the adequacy of surgical margins for basal cell carcinomas of this type.¹³³² Although the previous findings are promising, light microscopy is still the most reliable method of distinguishing trichoepithelioma from basal cell carcinoma, although the diffuse staining of basal cell carcinomas with bcl-2 is of some value.^{1333,1334}

Basaloid follicular hamartoma is another follicular proliferation that bears some histopathologic similarities to trichoepithelioma, infundibulocystic basal cell carcinoma, or Pinkus tumor. It may be seen as an autosomal dominant disorder, manifesting as multiple, smooth papular lesions on the face that are 1 or 2 mm in diameter or as a unifocal sporadic lesion.¹³³⁵ The cells of basaloid follicular hamartoma are somewhat larger than those of conventional trichoepithelioma or comparable basal cell carcinoma variants. They have a more distinctly squamoid appearance and assume a more prominent anastomosing growth pattern with interspersed horn cysts. Pigmented variants of this lesion also occur. Immunohistochemical staining for PCNA and Ki-67 is less in these tumors than is the case in basal cell carcinoma.¹³³⁶ Nevertheless, in small biopsies, or when there is incomplete clinical information, a distinction from basal cell carcinoma may be difficult or impossible. In such cases, diagnostic preference should probably be given to basal cell carcinoma, although the editor commonly mentions the resemblance to basaloid follicular hamartoma in an accompanying note.

Basaloid sebaceous carcinoma must be distinguished from the basosebaceous type of basal cell carcinoma. This distinction is largely based on assessment of the differentiated sebocytes in each lesion. Basal cell carcinoma with sebaceous features contains easily found clusters of well-developed sebaceous cells that are typically, but not invariably, located toward the centers of tumor cell islands. In contrast, basaloid sebaceous carcinoma shows very few, if any, mature sebocytes, and these have a random distribution throughout the tumor mass. Unfortunately, both tumors have the capacity for nuclear palisading.¹³³⁷ Pagetoid involvement of the epidermis also favors an interpretation of sebaceous carcinoma, but this change is not invariably present. Diagnosis may be aided by lipid stains on frozen tissue sections or

immunostains for epithelial membrane antigen; sebaceous carcinomas show diffuse positivity with both methods,^{470,471} whereas basosebaceous basal cell carcinomas are reactive only in areas of obvious sebaceous differentiation. Ultrastructural studies reveal the widespread presence of intracytoplasmic lipid droplets only in sebaceous carcinoma.¹³³⁷

Variants of sweat gland carcinoma usually lack the epidermal connections that are evident in adenoid basal cell carcinoma. Still, the distinction between these entities can be extremely challenging; for example, several reported examples of 'eccrine' basal cell carcinoma actually appear to represent adenoid cystic carcinomas. Sweat gland carcinomas do not manifest the fibromyxoid stroma or matrical retraction artifact of basal cell carcinoma. The finding of even a few melaninized cells or rudimentary foci of pilar keratinization in an adenoid basal cell tumor argues against the diagnosis of a sweat gland carcinoma. Immunostains for carcinoembryonic and epithelial membrane antigens are also extremely helpful because they are consistently positive in sweat gland carcinoma and negative in basal cell carcinoma.^{1338,1339} Mino and co-workers found that there is significantly less c-kit (CD117) expression in basal cell carcinoma than in adenoid cystic carcinoma.¹³⁴⁰ On ultrastructural examination, glandular (microvillous) differentiation is seen in sweat gland tumors but not in basal cell carcinoma. Adenoid basal cell carcinoma can be distinguished from adenoid cystic carcinoma through its epidermal or adnexal connections and lack of perineural invasion.¹³⁴¹ The rare primary cutaneous cribriform apocrine carcinoma differs by the lack of epidermal connections, peripheral palisading, or retraction artifact; more pleomorphic cells arranged in solid nests and tubules; papillary projections within tubules; and decapitation secretion within ducts.^{1341,1342}

Small, superficial biopsies of atypical keratinocyte neoplasms often show equivocal changes in which a morphologic distinction between basal cell carcinoma and proliferative actinic keratosis or squamous cell carcinoma can be quite difficult. BerEp4 has been used in such cases because it is typically positive in basal cell carcinoma. However, Yu and colleagues found that cords of squamoid cells in superficial biopsies of basal cell carcinoma are often negative for BerEp4, so staining results with this marker should be interpreted with caution.¹³⁴³ Evaluation of dermal changes can be helpful in the differential diagnosis of superficial basal cell carcinoma (frequently a fibromyxoid stroma), melanoma *in situ* (perifollicular infiltrate and periadnexal fibrosis), and actinic keratosis (lichenoid inflammatory infiltrate), especially when the tumor is not visible.¹³⁴⁴ Small-cell (basaloid) squamous cell carcinoma shows a lesser degree of nuclear palisading than basal cell carcinoma and typically lacks a fibromyxoid stroma. Tumor cell nuclei in small-cell squamous cell carcinoma are vesicular with prominent nucleoli, as opposed to the generally compact, anucleolated forms of basal cell carcinoma.¹³⁴⁵ The distinction between basaloid squamous cell carcinoma and basal cell carcinoma is particularly important in perianal skin, where true basal cell carcinoma must be differentiated from cloacogenic carcinoma. The latter tumor is highly aggressive compared to basal cell carcinoma. When confronting this diagnostic dilemma, immunostaining for BerEp4 can be most helpful because of the strong, diffuse expression of this antigen in basal cell carcinoma and the negative results in squamous cell carcinoma.¹³⁴⁶ Basal cell carcinoma cells stain with the murine monoclonal antibody VM-1;¹³⁴⁷ they usually do not stain for involucrin, epithelial membrane antigen, or CD44, as occurs in squamous cell carcinomas,¹³⁴⁸⁻¹³⁵² although CD44 has been found in infiltrative tumor strands.¹³⁵³ D2-40, a marker of lymphatic endothelium, is expressed in 65% of basal cell carcinomas and also in squamous cell carcinomas.¹³⁵⁴ As noted previously in the discussion of basal cell carcinoma versus sebaceous carcinoma, the former tumor is negative for EMA, except focally in squamous and keratotic areas.¹¹⁷⁹

Clear cell basal cell carcinoma can mimic a variety of other cutaneous tumors, including trichilemmal carcinoma, melanoma, sebaceous carcinoma, or clear cell eccrine tumors.¹²²¹ A variety of clear cell

tumors of extracutaneous origin should also be considered, as was demonstrated in the recent case of a pulmonary metastasis of clear cell basal cell carcinoma, in which other considerations included clear cell carcinoma of salivary gland (the patient had a mass in the left parotid region), mucoepidermoid carcinoma, or metastatic clear cell carcinomas of renal, adrenal, or thyroid origin.¹²²² The finding of peripheral palisading of tumor islands, retraction artifact, and positive staining for BerEP4 and bcl-2 confirmed the diagnosis of basal cell carcinoma.¹²²² Similar morphologic findings, as well as BerEP4 positivity and lack of S100 staining, help in distinguishing granular cell basal cell carcinoma from other granular cell tumors.¹²¹⁶ Another variant of basal cell carcinoma can show central nuclear palisading, creating a resemblance to schwannoma. However, peripheral palisading of tumor cell nuclei and stromal retraction are usually also present, and in contrast to true schwannoma, tumor cells are positive for keratin (AE1 and AE3) and negative for S100.¹²³⁸

Cytologic examination of pigmented basal cell carcinomas shows cohesive sheets, branching strands, and club-shaped aggregates of small basaloid cells with peripheral palisading and pigment both inside and peripheral to the epithelial fragments. This image differs from melanoma (loosely cohesive cells that vary in size and shape, eccentric nuclei with macronucleoli, and atypical mitoses), seborrheic keratoses (anucleate squames as well as squamous and basaloid cells), basaloid squamous cell carcinoma (clumped chromatin, parachromatin clearing, prominent nucleoli, mitoses, and necrosis), adenoid cystic carcinoma (three-dimensional clusters, finger-like tissue fragments, and cribriform sheets surrounding hyaline globules), small cell neuroendocrine carcinoma (dispersed atypical cells with nuclear molding, pleomorphism, mitoses, and necrosis), and the basaloid component of pilomatricoma (shadow cells, multinucleated cells, and calcific material).¹¹⁴³

NEVOID BASAL CELL CARCINOMA SYNDROME

The nevoid basal cell carcinoma syndrome (basal cell nevus syndrome, Gorlin's syndrome; OMIM 109400) is a multisystem disorder characterized by multiple basal cell carcinomas with an early age of onset, odontogenic keratocysts (now termed keratocystic odontogenic tumor to emphasize the neoplastic characteristics of this lesion), pits on the palms and/or soles, cutaneous cysts,¹³⁵⁵ skeletal and neurological anomalies, and ectopic calcifications.^{1356–1360} Atlanto-occipital ligament calcification¹³⁶¹ and elongated styloid process¹³⁶² have been described. Often, there is a characteristic facies, with hypertelorism and an enlarged calvaria.¹³⁶³ Less common manifestations include lipomas and fibromas of various organs,¹³⁶⁴ fetal rhabdomyoma,¹³⁶⁵ unilateral renal agenesis,¹³⁶⁶ adenoid cystic carcinoma of minor salivary gland,¹³⁶⁷ ovarian cysts, and medulloblastomas.^{1356,1368} Its prevalence is estimated to be 1 in 57,000 to 1 in 164,000.^{1369,1370} The inheritance is autosomal dominant with high gene penetrance and variable expressivity.¹³⁷¹ The responsible gene, the *PTCH1* gene, is at chromosome 9q22.3.^{1372–1374} A mutation in *PTCH2* on chromosome 1 has been described in this syndrome.¹³⁷⁰ More than 100 different mutations of *PTCH1* have now been reported.^{1369,1375} Total deletion of the gene has also been described.¹³⁷⁶ Sporadic cases of basal cell carcinoma with various mutations in genes of the sonic hedgehog pathway have been found (discussed previously).¹⁰⁰⁷ The *PTCH1* gene product is part of a receptor for a protein called sonic hedgehog (SHH), which is involved in embryonic development. When SHH binds to PTCH, it releases smoothened (SMO), a transmembrane signaling protein.¹⁰¹⁶ SMO in turn signals to GSK3 β , which phosphorylates Gli-3. SOX9 is another downstream target of the SHH pathway.¹⁰¹⁷ The PTCH protein is important in skin homeostasis.¹³⁷⁷ The molecular aspects of basal cell carcinoma were reviewed in an excellent article in 2005 by Tili *et al.*¹⁰¹⁸

Only 15% of affected individuals have basal cell carcinomas before puberty, and these may take the form of pigmented macules resembling nevi.¹³⁵⁶ More than 90% of patients with this syndrome have basal

cell carcinomas by the age of 40 years. The development of acrochordon-like basal cell carcinomas may be the first manifestation of the syndrome.¹³⁷⁸ Tumors are usually harmless before puberty, and only a small percentage become aggressive in later life.^{1363,1379} The tumors may develop anywhere, including within the palmar pits^{1380,1381} and on the perineum,¹³⁸² but there is a predilection for sun-exposed areas, such as the face, neck, and upper part of the trunk.¹³⁸³ They may vary in number from few to hundreds of lesions. A defective *in vitro* cellular response to X-irradiation has been found in the syndrome,¹³⁸⁴ and this may help explain the development of skin tumors in these patients at sites of X-irradiation.^{1380,1385}

The unilateral linear basal cell nevus is an unrelated condition that may be associated with comedones and, rarely, osteoma cutis.¹³⁸⁶ Mutations in the *PTCH* and *SMO* genes are not involved in this condition, confirming that it is a separate entity (see p. 764).^{1387,1388}

Multiple basal cell carcinomas can occur in a familial setting without other manifestations of a systemic syndrome. In one such family, segmental distribution of the tumors occurred representing mosaicism.¹³⁸⁹ Tissue and tumor mosaicism of the myotonin protein kinase gene located at 19q13.3 was found in a patient with multiple basal cell carcinomas associated with myotonic dystrophy.¹³⁹⁰ This association with myotonic dystrophy had been reported previously.¹³⁹⁰ A recent case report describes a patient with a mild phenotype of basal cell nevus syndrome, basaloid follicular hamartomas in a blaschkoid distribution, and the absence of the *PTCH* mutation.¹³⁹¹ Multiple hereditary infundibulocystic basal cell carcinomas have also been reported. Genetic studies have mapped the defect to chromosome 9q22.3, flanking the *PTCH* gene.¹¹⁶⁷ Cases with overlap features between these various types of multiple basal cell carcinoma syndromes have been described.¹³⁹² Photoprotection is practiced by patients with this syndrome, but the disadvantage of this is that vitamin D deficiency is common among these patients.¹³⁹³ A patient with severe manifestations of nevoid basal cell carcinoma syndrome showed a favorable therapeutic response to GDC-0449, an inhibitor of the Hedgehog signaling pathway.¹³⁹⁴

Histopathology¹³⁹⁵

The whole spectrum of histological variants of basal cell carcinoma is found in the nevoid basal cell carcinoma syndrome.¹³⁹⁶ Calcification, keratinizing cysts, pigmentation, and osteoid tissue have all been said to occur more frequently in basal cell carcinomas occurring in the syndrome than in sporadic cases, although some studies have failed to confirm this.¹³⁹⁶

The cutaneous cysts usually take the form of epidermal cysts.¹³⁵⁵ Occasionally, they may have a festooned lining of squamous cells that form keratin without the presence of a granular layer, thus resembling the keratocysts of the jaws.¹³⁹⁷ The keratocystic odontogenic tumor expresses podoplanin (D2-40), showing linear staining of basal epithelial cells.¹³⁹⁸

The palmar and plantar pits show marked thinning of the stratum corneum, with a thin parakeratotic or orthokeratotic layer in the base and variable hypogranulosis overlying a mildly acanthotic epidermis.^{1399,1400} Keratinocytes in the spinous layer may display pallor with vacuolated cytoplasm.¹⁴⁰⁰ Basal cell hyperplasia is observed, with crowding, palisading, and budding that resembles superficial basal cell carcinoma. In one reported case, areas of basal cell hyperplasia were positive for Ber-EP4 and TDAG51 (PHLDA1) – the latter marking the pleckstrin homology-like domain family A member 1 protein, involved in the anti-apoptotic effects of insulin-like growth factor-1 – and negative for androgen receptor; opposite results for TDAG51 and androgen receptor would be expected in basal cell carcinoma. The findings suggest that the basal cell hyperplasia of palmar pits does not represent basal cell carcinoma but, rather, a form of abnormal adnexal differentiation.¹⁴⁰⁰

SQUAMOUS CELL CARCINOMA

Squamous cell carcinoma is the second most common form of skin cancer in white people.¹⁴⁰¹ Its incidence in an Australian study was 166 cases per 100,000 of the population, the highest in the world;¹⁴⁰² in Scotland, it is 34.7 cases per 100,000.¹⁴⁰³ Its incidence has been increasing in many countries,¹⁴⁰⁴ but recent evidence suggests that the rate of increase may now be declining. Because it is rare for a cancer registry to record data on non-melanoma skin cancers, it is difficult to obtain accurate and comparable data on the true incidence of these cancers.¹⁴⁰⁵ However, it is estimated that 400,000–600,000 cases of squamous cell carcinoma of the skin occur worldwide each year.¹⁴⁰⁶ There is a predisposition for it to arise in the sun-damaged skin of fair-skinned people who tan poorly.^{1402,1407,1408} It is relatively uncommon in black people, in whom the tumors often arise in association with scarring processes.¹⁴⁰⁹ It is often associated with increased morbidity and mortality in black people. Skin cancer in skin of color was reviewed in 2006.¹⁴¹⁰ A detailed presentation of diagnostic and treatment guidelines for cutaneous squamous cell carcinoma was published in 2011.¹⁴¹¹

Clinical aspects

Most squamous cell carcinomas arise in areas of direct exposure to the sun, such as the forehead, face, neck, and dorsum of the hands.^{1412–1418} The ears, scalp, and vermillion part of the lower lip are also involved, particularly in males.¹⁴¹² Organ transplant recipients with lesions on the scalp are a high-risk group.¹⁴¹⁷ Non-exposed areas such as the buttocks, genitalia,^{1418,1419} and subungual regions^{1420–1427} are occasionally affected. Lesions on the lower limbs are more frequently seen in elderly women.^{1428,1429} Penile cancer is uncommon in the Western world. Most cases are squamous cell carcinomas, of which 5–16% are of verrucous type.¹⁴³⁰ Delayed presentation of squamous cell carcinoma may result in autodestruction of the penis.¹⁴³¹ Uncommonly, squamous cell carcinomas may develop at sites of chronic ulceration,¹⁴³² trauma, burns, frostbite,¹⁴³³ vaccination scars,^{1434,1435} tattoos,¹⁴³⁶ a pyoderma gangrenosum scar,¹⁴³⁷ skin grafts,¹⁴³⁸ fistula tracts,¹⁴³⁹ a dilated pore,¹⁴⁴⁰ pilonidal sinuses of long standing,^{1441,1442} an epidermal cyst,¹⁴⁴³ hidradenitis suppurativa, and acne conglobata.^{1444,1445} The term ‘Marjolin’s ulcer’ has been used for cancers arising in sites of chronic injury or irritation such as scars, ulcers, and sinuses,^{1446–1449} although Marjolin did not describe the condition with which he is eponymously credited.¹⁴⁵⁰ Tumors arising in these circumstances are sometimes aggressive, and local recurrences are common.¹⁴⁴⁷ Metastasis also occurs.¹⁴⁵¹

There are isolated reports of the occurrence of squamous cell carcinomas in various conditions, such as dystrophic epidermolysis bullosa,^{1452,1453} epidermolysis bullosa acquisita,¹⁴⁵⁴ Hailey–Hailey disease,¹⁴⁵⁵ porokeratosis,^{1456,1457} discoid lupus erythematosus,¹⁴⁵⁸ lichen planus,^{1459–1461} a psoriatic nail bed,¹⁴⁶² erythema ab igne, leprosy,¹⁴⁶³ lupus vulgaris,^{1464,1465} Klippel–Treunay syndrome,¹⁴⁶⁶ lichen sclerosis et atrophicus,^{1467,1468} balanitis xerotica obliterans, Crohn’s disease,¹⁴⁶⁹ acrodermatitis chronica atrophicans, chronic lymphedema,¹⁴⁷⁰ benign lymphoepithelial lesion,¹⁴⁷¹ organoid and epidermal nevi,^{28,1472–1474} granuloma inguinale, lymphogranuloma venereum, poikiloderma,¹⁴⁷⁵ mycosis fungoides,¹⁴⁷⁶ epidermodysplasia verruciformis,¹⁴⁷⁷ acrokeratosis verruciformis, nonbullous congenital ichthyosiform erythroderma,¹⁴⁷⁸ and the Jadassohn phenomenon. They have also developed rapidly in patients with psoriasis or rheumatoid arthritis treated with etanercept, a TNF- α antagonist.^{1479,1480} Squamous cell carcinomas are also increased in frequency among patients with xeroderma pigmentosum, vitiligo, and albinism.^{1481–1484} Several cases have been associated with hypercalcemia.^{1485–1488} Skin cancers arising in patients with non-Hodgkin’s lymphoma are aggressive (high-risk) lesions.^{1489,1490} The colocalization of squamous cell carcinoma and follicular lymphoma has been reported.¹⁴⁹¹

Squamous cell carcinomas are found predominantly in older people;¹⁴⁹² they are rare in adolescence and childhood.¹⁴⁹³ Clinically, they present as shallow ulcers, often with a keratinous crust and elevated, indurated surrounds. The adjacent skin usually shows features of actinic damage. The acantholytic variant is usually a nodular tumor on the head or neck, and it is almost invariably misdiagnosed clinically as a basal cell carcinoma. It tends to be more aggressive than the conventional squamous cell carcinoma.¹⁴⁹⁴ Pigmented variants are rare.¹⁴⁹⁵ The metastatic potential of squamous cell carcinoma is considered after discussion of the histopathology.

Occurrence in organ transplant recipients

Patients whose immune status is deficient,^{1496,1497} particularly organ transplant recipients,^{1498–1506} are also predisposed to develop these tumors. It has been estimated that organ transplant recipients have a risk of developing squamous cell carcinoma of the skin that is 18–82 times that of the general population.^{1507,1508} The incidence of carcinoma of the lip is also increased in these patients.¹⁵⁰⁹ Squamous cell carcinoma is the predominant type of skin cancer in renal transplant recipients, with a squamous cell carcinoma:basal cell carcinoma ratio of up to 3:1 – a reversal of the usual ratio in the community.^{1000,1001} Patients also develop warts with varying dysplasia and verrucous keratoses with a putative viral contribution.⁹⁸⁶ In a significant number of these tumors, HPV-5 or HPV-8 is found, suggesting a role for the virus in the etiology of the skin cancers that result.⁹⁸⁶ The E6/E7 oncogenes of these EV strains of HPV appear to be involved in this carcinogenesis.¹⁵¹⁰ In genital lesions, HPV-16 and/or HPV-18 have been detected.^{1511,1512} HPV-16 appears to be a risk factor for squamous cell carcinoma of the head and neck.¹⁵¹³ HPV has been specifically excluded in some series of post-transplant skin cancers,^{1514,1515} however, the frequency and spectrum of HPV types detected depend on the HPV detection system used, indicating a need for standardization of techniques.¹⁵¹⁶ There may be a synergistic interaction of HPV and HIV in the carcinogenic process leading to the development of some penile carcinomas.¹⁵¹⁷ It appears that background levels of p53 mutations may be increased in the normal skin of post-transplant and HIV patients, and this may contribute to the increased incidence of skin cancers in these patients.^{1518–1522} It should be remembered that the immunohistochemical overexpression of p53 does not necessarily reflect the degree of p53 gene mutations because short gene deletions will not be reflected in increased p53 immunoreactivity.¹⁵²³ There is also an increased telomere length in these patients, suggesting that telomere maintenance mechanisms should be further evaluated in organ transplant recipients.¹⁵²⁴ The tumors often infiltrate widely, indicating their aggressive nature. They have a diminished cellular immune response in the stroma.^{1525,1526} Low-dose retinoids produce a reduction in the number of skin cancers in these post-transplant patients.^{1527–1529} Its effects are short-lived in the treatment and prevention of premalignant lesions. Actinic keratoses recur soon after cessation of the drug.¹⁵³⁰ Most of the fatal cases have been reported from Australia, suggesting that sunlight, which has a profound effect on the cutaneous immune system,⁴⁴⁸ plays a role in the formation of these aggressive lesions.^{1500,1531} The triazole antifungal agent voriconazole is often used in transplant patients, but it is associated with phototoxicity. There have been a number of reports of squamous cell carcinomas among these patients.^{1532–1534} Long-term voriconazole is an independent risk factor for cutaneous squamous cell carcinoma in patients following lung transplantation.¹⁵³⁵ Transplant recipients are often poorly compliant with the use of sunscreens both before and after transplantation.^{1536,1537} Exposure to sunlight before the age of 30 years appears to be a risk factor for the development of skin cancers in renal transplant recipients,¹⁵³⁸ although not necessarily for aggressive malignancies. Other factors, such as the nature of the underlying disease that led to the need for transplantation, may play a role in predisposing to the development of skin cancer.

Patients with diabetes mellitus appear to have a lower incidence of skin cancer than those who had polycystic kidney disease and cholestatic liver disease. Information now indicates that recipients of cardiopulmonary transplants have a greater risk of developing aggressive cutaneous malignancies than do recipients of renal transplants.¹⁵³⁹ Cardiac transplant patients generally receive quantitatively more immunosuppression than their renal counterparts, and this is the presumed explanation for the significant incidence of cutaneous malignancies in this group.^{1539–1541} In a 2004 study, the risk of squamous cell carcinoma but not of basal cell carcinoma in heart transplant recipients was related to the level of global immunosuppression rather than to one specific drug.¹⁵⁴² Cessation of immunosuppressants appears to result in deceleration of cutaneous carcinogenesis.¹⁵⁴³ Reduction of immunosuppression is considered a reasonable adjuvant strategy in solid organ recipients who have substantial morbidity and mortality risk from skin cancer.^{1544–1546} An update on the pathogenesis of skin cancer in renal transplant recipients was published in 2008.¹⁰⁰⁰

Etiology

UVB radiation appears to be the most important etiological factor; UVA plays a minor role.^{663,1547–1552} A careful review of the literature and meta-analysis has shown consistent epidemiologic evidence for the positive association linking occupational UV light exposure and risk for squamous cell carcinoma.¹⁵⁵³ Intentional tanning was considered to be a contributing factor to the increase in tumors on covered sites in a Swedish population.¹⁵⁵⁴ UVB phototherapy appears to produce no significant risk for the subsequent development of skin cancer,¹⁵⁵⁵ but PUVA therapy for genital psoriasis has been followed by an increase in genital skin cancers.¹⁵⁵⁶ UV radiation is known to damage the DNA of epidermal cells, but there appear to be other complex mechanisms involved in UV-induced carcinogenesis. *P53* is a tumor suppressor gene, the mutation of which has been involved in the genesis of various cancers, including skin cancer.^{1557–1559} Mutant *p53* accumulates in the cell nucleus, and it can be demonstrated by immunohistochemical methods. Expansion of *p53* in the epidermis correlates with sun exposure and sun damage.¹⁵⁶⁰ Ionizing radiation also induces *P53* mutations.¹⁵⁶¹ It is increased in actinic (solar) keratoses and squamous cell carcinomas arising on sun-damaged skin.^{1557,1562,1563} A different molecular mechanism may be involved in the development of squamous cell carcinomas in sun-protected areas.¹⁵⁵⁷ Heat shock protein 105 is overexpressed in squamous cell carcinoma but not in basal cell carcinoma.¹⁵⁶⁴ EGFR is expressed in a minority of tumors.¹⁵⁶⁵ Squamous cell carcinomas can be produced in various animals with UV radiation, almost to the exclusion of other types of tumors.^{1548,1566} COX-2 inhibitors are an effective chemopreventive agent in UV carcinogenesis.^{1567,1568} COX-2 expression and angiogenesis are both early events in the development of squamous cell carcinoma.^{1569,1570} Regular users of nonsteroidal anti-inflammatory drugs (NSAIDs) have lower risks of developing squamous cell carcinomas and actinic keratoses than non-users. That is, NSAIDs have a protective effect.¹⁵⁷¹

Recent work has shown that the JNK cascade is activated in a majority of human squamous cell carcinomas and represents a potential therapeutic target for human epithelial cancers.¹⁵⁷² The JNK (mitogen-activated protein kinase 7 (MKK7)/C-JUN-NH(2)-kinase (JNK)/activator protein 1 (AP1)) cascade is activated by the TNF- α receptor (TNFR1).¹⁵⁷²

Less important etiological agents include radiation therapy,⁸⁷³ arsenic, smoking,¹⁵⁷³ coal tar, and various hydrocarbons.¹⁵⁷⁴

HPV may play a role in immunosuppressed patients (discussed previously);^{986,1511} it has a significant role in genital lesions and, rarely, in squamous cell carcinomas on the finger.^{1515,1575–1580} HPV-associated digital squamous cell carcinoma has a high rate of recurrence but a low rate of metastasis.^{1581,1582} HPV is now being detected in squamous cell

carcinomas of immunocompetent patients.^{1583–1587} Both β and γ HPV strains appear to be involved.¹⁵⁸⁸

As previously mentioned, etanercept therapy for rheumatoid arthritis has been associated with the development of squamous cell carcinoma, although another study found no risk.¹⁵⁸⁹ Sorafenib (a multikinase inhibitor), alone or in combination with tipifarnib (a farnesyl-transferase inhibitor), can result in the development of multiple squamous cell carcinomas of the skin.¹⁵⁹⁰ Topical tacrolimus and pimecrolimus are probably not of etiological significance.¹⁵⁹¹ No etiology is apparent in some cases of squamous cell carcinoma.¹⁵⁹²

The screening of workers with elevated exposure to UV radiation for skin cancer is surprisingly poor, considering that these workers are known to be at risk for the development of skin cancer.^{1593–1595}

Genetic aspects

The role of gene mutations in the development of this skin cancer is now being studied. It is well-known that unique mutations in the *P53* tumor suppressor gene are linked to the development of NMSCs in patients who have had exposure to UV radiation (discussed previously). The *CDKN2A* gene on chromosome 9p21 plays an active role in the *p53* and retinoblastoma (*rb*) tumor suppressor pathways.¹⁵⁹⁶ In addition to mutations in the *P53* gene, loss of expression of *CDKN2A* via deletion also plays a role in the pathogenesis of human NMSC.^{1596,1597} These deletions in *CDKN2A* may arise spontaneously during tumor progression. Inactivation of both genes is also common in carcinomas of the external genital organs.¹⁵⁹⁸ The genomic loss of 18q may be a significant event in the progression of solar keratosis to squamous cell carcinoma.¹⁵⁹⁹ Chromosomal instability at 13q14 adjacent to the retinoblastoma tumor suppressor gene (*Rb*) has been detected in some cases.¹⁶⁰⁰ Inactivation of the *Rb* gene can result from interaction with some HPV types.^{1600,1601} Dysregulated DNA mismatch repair is present in some NMSCs, particularly squamous cell carcinomas.^{1602–1604} Allelic imbalance/loss of heterozygosity occurs in the *BRCA2* gene region in some cases of cutaneous squamous cell carcinoma.¹⁴⁰⁶ Aberrations in the fragile histidine triad (*FHIT*) gene have also been reported in cutaneous squamous cell carcinomas.¹⁶⁰⁵ It should be kept in mind that, in simple terms, carcinogenesis is a three-step process that consists of initiation, promotion, and progression.¹⁶⁰⁶

Unitarian theory of squamous cell carcinoma

Ackerman proposed that solar keratoses should be regarded as squamous cell carcinomas *de novo* and that they should not be regarded as premalignancies or precancers that may convert into squamous cell carcinoma.^{471,1607} Others have agreed with this approach.^{1608,1609}

According to this 'unitarian' viewpoint, the following conditions are morphological expressions of squamous cell carcinoma:

- Solar keratosis and its analogues, arsenical and radiation keratoses
- Bowen's disease and bowenoid papulosis
- Giant condyloma and verrucous carcinoma
- Keratoacanthoma
- Proliferating trichilemmal cysts.

However, this approach assumes the inevitable progression of solar keratoses to squamous cell carcinomas, which is not proved. It is also likely to alarm patients who have one of these lesions. This approach also has a significant impact on reimbursement schedules in some jurisdictions.

Treatment of squamous cell carcinoma

Where feasible, surgical excision (including Mohs surgery where appropriate) is the treatment of choice. Surgery is also the treatment of choice for lesions arising in leg ulcers^{1449,1451} and for lesions of the nail apparatus.¹⁴²⁶ Mohs surgery is superior to traditional surgery particularly for high-risk and facial lesions. In an Australian study of 1263

cutaneous squamous cell carcinomas treated by Mohs surgery, the 5-year recurrence rate was 2.6% for primary lesions and 5.9% for patients with recurrent lesions.¹⁶¹⁰ Radiotherapy has been used for lesions of the ear, lip, and nasal vestibule where cosmetic results are important. For locally advanced lesions, chemoradiation has been used.¹⁶¹¹ The chemotherapeutic agents in one series were low-dose cisplatin and 5-fluorouracil.¹⁶¹¹ In organ transplant recipients with many tumors, curettage and electrodesiccation can be a safe therapy for appropriately selected low-risk lesions.¹⁶¹² Cryotherapy can also be used for small lesions, but it is not appropriate for recurrent disease.¹⁶¹³

Histopathology

The usual squamous cell carcinoma consists of nests of squamous epithelial cells that arise from the epidermis and extend into the dermis for a variable distance. The cells have abundant eosinophilic cytoplasm and a large, often vesicular, nucleus. There is variable central keratinization and horn pearl formation, depending on the differentiation of the tumor. Individual cell keratinization is often present. The degree of anaplasia in the tumor nests has been used to grade squamous cell carcinomas. Usually, a rather subjective assessment of differentiation is made using the categories of 'well', 'moderately', and 'poorly' differentiated rather than Broder's classic grading of 1–4, where grade 4 applies to the most poorly differentiated lesions (Fig. 31.33). Surprisingly, only 54% of dermatopathologists in one study graded squamous cell carcinomas.¹⁶¹⁴

Most squamous cell carcinomas arise in solar keratoses or sun-damaged skin.^{1054,1615,1616} The borderline between a thick solar keratosis and a superficial squamous cell carcinoma is somewhat arbitrary (see p. 797). The interobserver concordance for these lesions is lower than that for basal cell carcinoma.¹⁶¹⁷ Ackerman proposed that very superficial squamous cell carcinoma 'should be termed just that'.¹⁶¹⁸ Squamous cell carcinomas sometimes arise in Bowen's disease, and in these cases the cells are usually nonkeratinizing; they may show variable trichilemmal or even sebaceous-like differentiation.⁶⁵⁸ These tumors should not be confused with the rare clear cell^{1221,1619–1621} and 'signet-ring'^{1622–1624} variants of squamous cell carcinoma, both of which have cells with pale cytoplasm; in the case of the 'signet-ring' variant, the nucleus is eccentric. The situation in the vulva is different. VIN is found adjacent to squamous cell carcinomas in up to 80% of cases. Many of these tumors are of the classic keratinizing type.¹⁶²⁵ Although warty and basaloid tumors were once regarded as an indication of HPV infection, and keratinizing lesions a feature of non-HPV-related squamous cell carcinomas of the vulva, many exceptions occur.¹⁶²⁶

Figure 31.33 Moderately well-differentiated squamous cell carcinoma. (H&E)

Immunostaining for p16 is a reliable marker for HPV-positive tumors at this site.¹⁶²⁷ Tumors developing in renal transplant recipients cannot be reliably distinguished from those arising in immunocompetent people,¹⁶²⁸ although in one study there was a decreased density of peritumoral inflammatory cells in transplant recipients.¹⁶²⁹ This was postulated to be the reason for their more aggressive behavior.¹⁶²⁹

Squamous cell carcinomas occasionally infiltrate along nerve sheaths, the adventitia of blood vessels, lymphatics, fascial planes, and embryological fusion planes.^{1630,1631} The presence of perineural lymphocytes is an important clue to the likely presence of perineural invasion in deeper sections.¹⁶³² There is often a mild to moderate chronic inflammatory cell infiltrate at the periphery of the tumor.¹⁶³³ A subpopulation of these cells express the TCR- $\alpha\beta$ heterodimer.¹⁶³⁴ Eosinophils are occasionally prominent in the infiltrate and sometimes extend into the tumor islands.¹⁶³⁵ Erythrophagocytosis by tumor cells has been reported in one case.¹⁶³⁶ The tumor cells may evoke a stromal desmoplastic response.¹⁶³⁷ Stromal components may be important in regulating the growth of some tumors.¹⁶³⁸

Little mention has been made in the literature of vascular invasion by squamous cell carcinoma. The author has seen approximately 10 cases of this phenomenon involving both venules and small arteries. It may result in a tumor thrombus occluding the vessel.¹⁶³⁹

Immunoperoxidase studies are sometimes helpful if the tumor is poorly differentiated or of spindle cell type.¹⁶⁴⁰ The cells are positive for epithelial membrane antigen,^{1178,1641} MNF116, and cytokeratin 5/6.^{1339,1642} Squamous cell carcinomas contain keratins of higher molecular weight than those in basal cell carcinomas.¹⁶⁴³ Involucrin is present in larger keratinized cells.¹³⁴⁸ Tumor cells do not express Ber-EP4 or CD10, in contrast to basal cell carcinomas, which do.¹¹²¹ Some sarcomatoid squamous cell carcinomas may express CD10. Stains for lysozyme, S100 protein, and desmin are negative. Vimentin may be expressed in poorly differentiated and spindle cell variants (see later). The expression of Ki-67, MIB-1, and vascular endothelial growth factor is higher in squamous cell carcinoma than in basal cell carcinoma.^{1644,1645} However, the level of expression of Ki-67 and MIB-1 is not a predictor of prognosis.¹⁶⁴⁶ Positive staining for p63 is a highly specific marker for squamous cell carcinoma.¹⁶⁴⁷ Minichromosome maintenance 5 protein (MCM5) is expressed in nearly 80% of cells in a squamous cell carcinoma. It is a useful marker to detect cell proliferation in skin sections.¹⁶⁴⁸ CK20 was expressed in two cases of signet-ring cell carcinoma.¹⁶⁴⁹

Spindle cell squamous carcinoma

Spindle cell squamous carcinoma is an uncommon variant that usually arises in sun-damaged or irradiated skin. A spindle cell morphology is more common in squamous cell carcinomas arising in organ transplant recipients.¹⁶⁵⁰ Rare cases occur on the vulva,¹⁶⁵¹ where spindle cell squamous cell carcinoma has a worse prognosis than conventional squamous cell carcinoma.¹⁶⁵² A spindle cell squamous cell carcinoma arising in nevus sebaceus has been described.¹⁶⁵³ It may be composed entirely of spindle cells or have a variable component of more conventional squamous cell carcinoma.^{1654–1658} Basosquamous and spindle cell differentiation in the same lesion has been reported.¹⁶⁵⁹ In another case, an infiltrative basal cell carcinoma recurred as a spindle cell carcinoma.^{1660,1661} The spindle cells have a large vesicular nucleus and scanty eosinophilic cytoplasm, often with indistinct cell borders (Fig. 31.34). There is variable pleomorphism, usually with many mitoses. The presence of squamous differentiation, dyskeratotic cells, and continuity with the epidermis may assist in making the diagnosis. Electron microscopy and immunoperoxidase markers may be necessary in some circumstances to differentiate this variant from malignant melanoma and atypical fibroxanthoma.^{1662–1665} Some spindle cell squamous carcinomas may coexpress cytokeratin and vimentin, suggesting metaplastic change of a squamous cell carcinoma to a neoplasm with mesenchymal

Figure 31.34 Squamous cell carcinoma of spindle cell type. (H&E)

characteristics.^{1666,1667} Vimentin is sometimes found in squamous cell carcinomas arising in Marjolin's ulcers.¹⁶⁶⁸ Because the spindle cells are often negative with CAM5.2, it is necessary to use a pankeratin marker or 'cocktail'. MNF116 is suitable for this purpose. Another useful marker for this variant is p63.¹⁶⁶⁹ In one study of 16 cases, 6 cases expressed AE1/AE3, whereas 11 expressed CK5/6.¹⁶⁷⁰ In a recent study, p63 was expressed in 10 of 12 cases, and the cytokeratin marker 34 β E12 was expressed in all 12 cases.¹⁶⁷¹ It appears to be a promising marker for spindle cell squamous carcinoma. HER2 is not expressed.¹⁶⁷²

Adenoid squamous cell carcinoma

The adenoid (acantholytic, pseudoglandular) variant, which is found most often on the head and neck, accounts for 2–4% of all squamous cell carcinomas.^{1658,1673–1676} It consists of nests of squamous cells with central acantholysis leading to an impression of gland formation,¹⁶⁷³ although the peripheral cells are cohesive (Fig. 31.35). Acantholysis is sometimes minimal. Mucin has been reported in some,¹⁶⁷⁵ but these tumors may have been variants of adenosquamous carcinoma (see p. 823). Adenoid variants often arise from an acantholytic solar keratosis. Sometimes this is in the vicinity of the pilosebaceous follicle.¹⁶⁷⁵

Pseudovascular squamous cell carcinoma

Pseudovascular squamous cell carcinoma is a rare variant of adenoid squamous cell carcinoma that may be mistaken for an angiosarcoma.¹⁶⁷⁷ The terms 'pseudovascular adenoid squamous cell carcinoma'¹⁶⁷⁸ and 'pseudoangiosarcomatous carcinoma'^{1679,1680} have also been used for this tumor. It presents as an ulcer or crusted nodule on sun-exposed skin. It has also been reported on the vulva.¹⁶⁸⁰ The tumor usually has an aggressive behavior, with a high mortality rate.¹⁶⁸¹ Microscopically, the lesion is composed of pseudovascular structures lined by cords of polygonal or flattened tumor cells (Fig. 31.36).¹⁶⁷⁸ The cells express cytokeratin (AE1/AE3 and 34 β E12), epithelial membrane antigen, and, sometimes, vimentin.^{1680,1682} They are negative for CD31, CD34, and factor VIII-related antigen.¹⁶⁷⁸

Other variants of squamous cell carcinoma

There are several other histological variants of squamous cell carcinoma, a knowledge of which may prevent misdiagnosis. The *clear cell* and *'signet-ring'* types have already been mentioned. The cells express keratin markers.¹⁶²³ The relationship between clear cell carcinoma of the skin and trichilemmal carcinoma is controversial. The existence of

Figure 31.35 Squamous cell carcinoma of adenoid (acantholytic) type. (A) The cells at the periphery of the tumor nests are still cohesive. (B) There is some variability in size of the acantholytic cells. (H&E)

trichilemmal carcinoma as originally described by Headington (see p. 921) has been questioned.^{1658,1683} As initially described, clear cell carcinoma of the skin is said to lack glycogen; however, 38 of 40 cases of squamous cell carcinoma with clear cells described by Dalton and LeBoit in 2008 had glycogen, but few cases had the other criteria proposed by Headington for trichilemmal carcinoma. Thus, a quandary remains: are clear cell carcinoma of Kuo, squamous cell carcinoma with clear cells of Dalton and LeBoit, and trichilemmal carcinoma of Headington all variants of the same entity? Clear cell carcinoma of the penis is a distinct variant of penile carcinoma.¹⁶⁸⁴

A *pigmented* variant also occurs.^{1495,1685} Melanin is found in epithelial tumor cells as well as in macrophages and dendritic melanocytes. The dendritic cells express S100 protein and HMB-45.^{1686–1691} This variant must be distinguished from the squamomelanocytic tumor, in which both a squamous cell carcinoma and melanoma component develop (see p. 900).

The *inflammatory* squamous cell carcinoma has a dense lymphocytic stromal infiltrate surrounding poorly differentiated squamous nests (Fig. 31.37). Focal regression is sometimes present. This variant appears to have a high metastatic potential.

The *pseudohyperplastic* variant is a nonverruciform lesion that occurs on the penis.¹⁶⁹² It is associated with lichen sclerosis of the foreskin. It is composed of well-differentiated keratinizing nests of

Figure 31.36 Pseudovascular squamous cell carcinoma. (A) There are cords of cells with intervening vascular spaces. (H&E) (B) The keratin stain confirms the squamous cell nature of the lesion. (C) A small cluster of cells has not stained, but the majority of cells are positive. (MNF116 immunoperoxidase stain)

Figure 31.37 Squamous cell carcinoma of inflammatory type. There is usually a heavy infiltrate throughout the entire tumor. (H&E)

Figure 31.38 Squamous cell carcinoma of follicular origin. (H&E)

squamous cells with minimal atypia surrounded by a reactive fibrous stroma.¹⁶⁹² It may mimic pseudoepitheliomatous hyperplasia on a biopsy.

The *follicular* squamous cell carcinoma is a poorly recognized neoplasm arising from the wall of hair follicles (Fig. 31.38).¹⁶⁹³ Sixteen cases of this variant were found in a series of 7000 cases of squamous cell carcinoma reviewed from Spain.¹⁶⁹³ Tumors develop in the upper part of the hair follicles with or without involvement of the epidermis bordering the infundibulum of the involved follicle.¹⁶⁹³ Due to its microscopic configuration, this variant must be distinguished from metastatic squamous cell carcinoma.¹⁶⁹⁴ The infundibulocystic (infundibular) squamous cell carcinoma is the term coined by Kossard

et al. for a tumor that in its well-differentiated form is probably a keratoacanthoma but that in its less differentiated form has probably been regarded as just a squamous cell carcinoma.¹⁶⁹⁵ It is closely related in some cases to what has been called follicular squamous cell carcinoma. An infundibulocystic hyperplasia that may progress to keratoacanthoma or squamous cell carcinoma has been seen in hypertrophic lichen planus.¹⁶⁹⁶ Based on their studies, Misago *et al.* proposed that follicular squamous cell carcinoma and the less differentiated infundibulocystic squamous cell carcinoma are the same disease, and they prefer the term follicular (or infundibular) squamous cell carcinoma for these conditions. They believe that the infiltrative variant of infundibulocystic squamous cell carcinoma is a distinct entity, featuring, as it does, numerous infundibular cysts infiltrating into the deep dermis and subcutis and lacking a central keratin-filled crater. It is this entity for which they prefer the designation infundibulocystic squamous cell carcinoma.¹⁶⁹⁷ Both they and Kossard believe that the latter lesion has features suggestive of a follicular variant of microcystic adnexal carcinoma.^{1697,1698} An additional problem raised by these studies is the place of keratoacanthoma within this conceptual framework. Kossard noted that less well-differentiated tumors can arise from clearly defined keratoacanthomas in a number of cases,¹⁶⁹⁹ and therefore a histogenetic link between these follicular tumors and keratoacanthoma should probably be maintained.¹⁶⁹⁸

The *basaloid* squamous cell carcinoma is a distinctive variant of squamous cell carcinoma found in the oropharynx¹⁷⁰⁰ and anogenital region.¹⁷⁰¹ In this latter region, it has a high association with HPV infection. It is composed of small basaloid cells with a high mitotic rate.¹⁷⁰¹ Central comedonecrosis is sometimes present in the tumor cell islands. It has a higher histological grade, deeper extension, and higher mortality rate than conventional tumors. However, HPV-16 positivity in basaloid tumors of the head and neck is associated with a better survival than tumors that are HPV negative.¹⁷⁰²

Other rare variants are the *infiltrative* type (Fig. 31.39), with small nests and strands or single cells infiltrating a dermis that is fibrous and/or mucinous,^{1703,1704} and a *desmoplastic* variant analogous to morpheic basal cell carcinoma.^{1705,1706} Examples of desmoplastic squamous cell carcinoma have been described consisting of fascicles of spindled cells, some with bland-appearing cytologic features, and reactive stromal cells. The diagnosis is made by recognizing deep, sometimes subcutaneous infiltration by pleomorphic cells, squamoid features, associated squamous cell carcinoma *in situ*, and positive immunostaining with a panel of cytokeratins and p63.¹⁷⁰⁷ A poorly differentiated squamous cell carcinoma with *osteoclastic giant cells* has been reported.^{1708,1709} The osteoclast-like cells strongly expressed CD68 but not cytokeratin.¹⁷⁰⁸ Finally, there have been reports of *rhabdoid* differentiation in a squamous cell carcinoma.^{1709,1710}

Electron microscopy

The tumor cells in conventional lesions have tonofilaments and well-developed desmosomes and some interdigitating microvilli. In some studies of spindle cell lesions, the cells have shown the features of squamous epithelium with well-developed desmosomes and tonofilaments.^{1711,1712} In other cases, there have been cells resembling fibroblasts, as well as cells exhibiting both mesenchymal and epithelial features.¹⁷¹³ This mixed pattern of differentiation may result from cell fusion rather than metaplasia.¹⁷¹³

Recurrences and metastases

Recurrences are more likely in those tumors with aggressive histological features such as deep invasion,¹⁷¹⁴ poor differentiation, perineural invasion, and acantholytic features.^{1281,1715–1718} Aneuploidy does not appear to correlate with the risk of metastasis.¹⁷¹⁹ Narrow surgical margins also contribute to local recurrence.¹⁷²⁰ Squamous cell carcinomas developing in patients who are immunosuppressed or who have

Figure 31.39 (A) Squamous cell carcinoma of infiltrative type. (B) There are strands and small clusters of cells infiltrating between collagenous bundles. (H&E)

an underlying malignant lymphoma or leukemia are often more aggressive.^{1721–1723} The majority of squamous cell carcinomas are only locally aggressive and are cured by several different methods of treatment. The recurrence rate is approximately double that for basal cell carcinomas.¹⁷²⁴

The risk of metastasis varies with the clinical setting in which the lesion arises.¹⁷²⁵ The lowest risk is for tumors arising in sun-damaged skin and less than 2 cm in diameter.^{1726,1727} The usually quoted figure of 0.5%¹⁷²⁶ has been challenged as being too low on the basis of several hospital series, which might be expected to be weighted in favor of more aggressive and deeply invasive lesions.¹⁵⁴⁸ In this regard, it appears that vertical tumor thickness is a prognostic variable, just as it is for melanomas,^{1714,1728} although further studies are required to ascertain the critical tumor thickness required for metastasis. Tumors greater than 4 or 5 mm thick are regarded as high-risk lesions.¹⁷²⁹ Acantholytic variants arising in sun-damaged skin have a slightly greater risk of metastasis, of the order of 2%,¹⁷²⁵ although in one study it was as high as 19%.¹⁶⁷⁶ Invasive lesions arising in Bowen's disease metastasize in 2–5% of cases.⁶⁵⁸ They have been regarded as high-risk squamous cell carcinomas.¹⁷³⁰ Poor differentiation, incomplete excision, and an immunosuppressed state are other high-risk features.¹⁷²⁹

For lesions arising in skin not exposed to the sun, the incidence of metastases is approximately 2 or 3%.^{1731,1732} There is a further increase in this risk for lesions of the lip, although the quoted range (2–16%) is quite wide.^{1728,1732–1734} Tumors of the lip are more likely to metastasize

if there is perineural invasion, if the tumor is of high grade with a dispersed pattern, and if the tumor thickness exceeds 2 mm.^{1728,1735} The presence of desmoplasia and an inflammatory response with eosinophils and plasma cells are two further adverse features.¹⁷³⁶ Metastasis is almost invariable for tumors thicker than 6 mm.¹⁷³⁵ Muscle invasion is not useful in predicting the development of lymph node metastases, as was once thought. Thickness of the primary lesion is also a determinant of metastatic potential in squamous cell carcinoma of the skin, in sites other than the lip. Metastasis does not occur in lesions less than 2 mm thick. Metastasis is unusual in tumors confined to the dermis, in the absence of perineural invasion.¹⁷³⁷ Measuring tumor thickness for all squamous cell carcinomas is advocated by some.¹⁷³⁷ The author usually does so for all tumors of the lip and for cutaneous lesions invading beyond the dermis. In a survey published in 2003, only 8% of dermatopathologists stated that they measured tumor thickness.¹⁶¹⁴ This parameter is listed as a requirement in the minimum data set produced by the Royal College of Pathologists.¹⁷³⁸ Tumor vascularity is not a risk factor for metastasis.¹⁷³⁹ A strong dendritic cell response appears to be favorable.¹⁷⁴⁰ In a retrospective review of 323 patients with squamous cell carcinoma of the lip, the cause-specific survival at 10 years was 98%.¹⁷⁴¹ For squamous cell carcinomas arising in Marjolin's ulcers, the incidence of metastasis is thought to be 10–30%,¹⁷³² whereas for vulvar, perineal, and penile tumors, it may be as high as 30–80%.^{1725,1742–1744} Carcinomas arising in scars, usually resulting from thermal burns, have been regarded in the past as having a higher metastatic rate than non-scar cancers, but this was not confirmed in a recent study, although the follow-up period was short.¹⁷⁴⁵

Perineural invasion can be divided into two types: incidental, which is detected on biopsy or excision in a patient who is asymptomatic; and clinical, which accounts for 30–40% of cases and in which the nerve invasion has produced clinical symptoms.¹⁷⁴⁶ Symptomatic patients can be further categorized into imaging-positive and imaging-negative groups.¹⁷⁴⁶ Radiotherapy gives good results for symptomatic, imaging-negative cases.¹⁷⁴⁶ In a study on penile squamous cell carcinomas, histological grade and perineural invasion were found to be more important than tumor thickness as predictors of nodal metastasis.¹⁷⁴⁷ In a series of 70 patients from Australia with squamous cell carcinoma and perineural invasion treated by Mohs surgery with adjunctive radiotherapy in 52.9% of cases, the subsequent 5-year recurrence rate was 8%, but only 25 patients had completed this period of follow-up.¹⁷⁴⁸

Metastases usually occur in the regional lymph nodes in the first instance. For this reason, sentinel lymph node biopsy has been advocated for some high-risk lesions.^{1749–1752} Uncommonly, the lung is involved, and then it is usually a terminal phenomenon associated with metastases to other organs. Cutaneous metastases are exceedingly rare.¹⁷⁵³ In one case, they produced a bowenoid (epidermotropic) pattern.¹⁷⁵⁴ A zosteriform pattern of cutaneous metastasis has also been recorded.¹⁷⁵⁵ A circulating tumor antigen, thought to be specific for squamous cell carcinoma, has been detected in patients with metastatic disease;¹⁷⁵⁶ however, this antigen has been reported recently in patients with inflammatory dermatoses.¹⁷⁵⁷ The possibility of a cutaneous metastasis from a visceral organ (e.g., the lung) should be kept in mind when a rapidly growing nodule presents in the skin.¹⁷⁵⁸

It has been suggested that tumor spread may be facilitated by a loss of skin-derived antileukoproteinase (SKALP), an inhibitor of elastase and proteinase 3. This enzyme is found in well-differentiated tumors but is absent in poorly differentiated tumor cells.¹⁷⁵⁹ Other factors undoubtedly contribute, such as reduced expression of the adherens junction protein vinculin¹⁷⁶⁰ and the surface proteoglycan syndecan-1.^{1761,1762} Upregulation of desmoglein-2 correlates with the risk of metastasis.¹⁷⁶³ There is increased expression of the MMPs (which degrade extracellular matrix),^{1072,1764} cathepsin B and D,^{1765,1766} carcinoembryonic antigen,¹⁷⁶⁷ and ornithine decarboxylase.¹⁷⁶⁸ The expression of p14 in vulvar carcinomas is associated with longer survival, whereas in patients with HPV-related tumors, the expression of

high levels of p53 and low p14 indicated the poorest 5-year disease-specific survival.¹⁷⁶⁹ Chemokine receptor expression may adversely affect the biological behavior of tumors.¹⁷⁷⁰ Several cases of burn scar-related squamous cell carcinoma, an aggressive variant, have had mutations in the *Fas* gene, involved in cell death signaling.¹⁷⁷¹ Apoptosis is increased in squamous cell carcinomas.¹⁷⁷² HPV of the same subtype as seen in the primary lesion can be detected in metastatic lesions.¹⁷⁷³

A study of the mortality risk from squamous cell carcinoma found that a lesion 4 cm or larger, histological evidence of perineural invasion, and deep invasion beyond subcutaneous structures were the features most significantly associated with disease-specific mortality in cutaneous lesions.¹⁷⁷⁴ The 3-year disease-free survival was 100% for patients with no risk factors versus 70% for patients with at least one of these three risk factors.¹⁷⁷⁴ Mortality risk for squamous cell carcinoma appears to be increasing.

A not uncommon problem is the finding of a predominantly cystic squamous cell carcinoma in the soft tissues of the neck. Often, no primary tumor can be found, although there may be a history of past skin cancers. One study showed that in the majority of cases, the primary lesion will be in the faucial or lingual tonsillar crypt epithelium.¹⁷⁷⁵

Differential diagnosis

Several problems arise in the diagnosis of squamous cell carcinoma, even in the face of an obvious keratinocyte neoplasm. One is determining the point at which an actinic keratosis has progressed to a superficially invasive squamous cell carcinoma. The key to diagnosis is the recognition that invasive tumor is truly present and that clusters of atypical keratinocytes do not simply represent cross-sectional profiles of prominent budding rete ridges. This distinction is at times somewhat arbitrary and probably makes little difference in terms of management, but determining invasion may be impossible when superficially shaved specimens are submitted for review. In such cases, a diagnosis of 'at least actinic keratosis' is appropriate. Another issue is the handling of large bulky keratinocyte neoplasms that are completely connected to the epithelial surface. Such lesions are probably better designated as squamous cell carcinomas even if unequivocal invasive tumor islands are not detectable. Acantholytic, adenoid, or pseudoglandular squamous cell carcinomas can be distinguished from true adenocarcinomas by more 'typical' changes of squamous cell carcinoma elsewhere, by the absence of epithelial mucin, and by a typical immunohistochemical profile for squamous cell carcinoma. The latter also facilitates distinction from angiosarcoma. The close clinical and histopathologic resemblance of spindle cell squamous cell carcinoma to atypical fibroxanthoma can be problematic; in fact, prior to the advent of immunohistochemistry, some experts believed they were one and the same. As noted previously, demonstration of unequivocal connections to the surface epidermis or foci of more characteristic squamous differentiation can aid in distinction, but cytokeratin staining of tumor cells may or may not be decisive. The marker CD10 generally stains atypical fibroxanthomas strongly and diffusely but unfortunately is not entirely specific for that condition, and positive staining is sometimes seen in spindle cell squamous cell carcinoma.¹⁷⁷⁶ Furthermore, p63 alone is not highly sensitive for squamous cell carcinoma.¹⁷⁷⁷ This has suggested to some the need for immunohistochemical staining panels, including several cytokeratin markers and p63, in addition to CD10, to make an accurate diagnosis.¹⁷⁷⁶ The absence of intracellular mucin aids in differentiating the rare signet-ring cell squamous cell carcinoma from similar-appearing adenocarcinomas. Another potential source of diagnostic confusion is the rare signet-ring cell carcinoma of the eyelids. The latter is thought to be a tumor of sweat gland origin and presents in middle-aged or elderly men as diffuse induration of the lids. It is biologically aggressive, with a high rate of regional or distant metastases. Tumor cells proliferate within a sclerotic stroma but may be

positive for estrogen and progesterone receptors and for milk fat globule protein.¹⁷⁷⁸ Differentiation of squamous cell carcinoma from pseudoepitheliomatous hyperplasia, keratoacanthoma, and irritated seborrheic keratosis (basosquamous acanthoma) is discussed in the sections concerning these lesions.

Occasionally, squamous cell carcinoma may be confused with basal cell carcinoma. This problem can arise in several situations: (1) Bowen's disease with invasive carcinoma, (2) pseudoepitheliomatous hyperplasia overlying a basal cell carcinoma, (3) true collision lesions with both basal and squamous cell carcinoma, and (4) the differentiation of basosquamous carcinoma from basaloid squamous cell carcinoma. With regard to the latter problem, three examples of basaloid squamous cell carcinoma arising in the skin have been presented by Boyd *et al.* Anatomic sites were the left forearm (1 case) and inguinal crease (2 cases). Keys to the diagnosis – and the distinction from basal cell carcinoma variants – were the expression of high-molecular-weight cytokeratins (34βE12 and cytokeratin 5/6) and negativity for Ber-EP4 and bcl-2.¹⁷⁷⁹ Both inguinal lesions had the HPV genotype 33.¹⁷⁷⁹ Basaloid squamous cell carcinomas metastatic to the skin but arising in extracutaneous sites (esophagus and larynx) have also been reported.^{1780,1781} An example of basaloid squamous cell carcinoma with 'monster cells', resembling those seen in basal cell carcinomas, has been reported; the tumor was Ber-EP4 and EMA⁺, in contrast to basal cell carcinoma.¹⁷⁸² A papillary variant of basaloid squamous cell carcinoma of the penis features papillae with fibrovascular cores and a well-demarcated base. Eleven of the 12 cases were HPV⁺; HPV-16 was present in 9 tumors.¹⁷⁸³ The overall prognosis tends to be good, although deeply invasive tumors were accompanied by regional nodal metastasis.¹⁷⁸³ Staining for Ber-EP4 alone may not be reliable in distinguishing basal cell carcinoma with squamous metaplasia from basaloid squamous cell carcinoma, but the addition of CK14 and CK17 stains improves diagnostic accuracy because no basaloid squamous cell carcinoma showed diffuse staining for all three markers.¹⁷⁸⁴ Still another study investigating the distinction between basal cell carcinoma and basaloid squamous cell carcinoma of the anal region suggested the following differentiating features: perianal location, retraction artifact, lack of atypical mitoses, and diffuse Ber-EP4 and bcl-2 staining (basal cell carcinoma); and origin from the anal canal, the presence of an *in situ* component, and diffuse CDKN2A and SOX2 staining (basaloid squamous cell carcinoma).¹⁷⁸⁵

VERRUCOUS CARCINOMA

Verrucous carcinoma was first described in the mouth by Lauren V. Ackerman in 1948.¹⁷⁸⁶ He regarded it as a distinctive variant of squamous cell carcinoma. In addition to the oral cavity,^{1787–1789} it may also involve the larynx, esophagus, and skin.^{1790–1792} It is a slow-growing, often large, warty tumor that invades contiguous structures but rarely metastasizes.¹⁷⁹³ Cutaneous lesions are usually in the genitocrural area^{1794–1798} or on the plantar surface of the foot (epithelioma cuniculatum), although exceptionally it can arise in any part of the skin surface.^{1799–1806} A verrucous carcinoma of the lip has been reported in a young pregnant woman.¹⁸⁰⁷ The synchronous development of verrucous carcinoma and cutaneous T-cell lymphoma has also been reported.¹⁷⁹⁸

Plantar lesions are the most common form of verrucous carcinoma.^{1808–1813} They are usually exophytic, pale lesions, sometimes with draining sinuses,¹⁸¹⁴ and they are often painful and tender. Similar lesions have rarely been reported on the palm or thumb.^{1815,1816} Some cases in these sites, and also on the penis, are microscopically endophytic, and the term epithelioma (carcinoma) cuniculatum is still used for tumors with this growth pattern.¹⁸¹⁷ HPV-31 and HPV-33 were isolated from a recurrent lesion of the finger with this growth pattern.¹⁸¹⁸

Seven cases of 'carcinoma cuniculatum' of the penis were reported recently.¹⁸¹⁷ None of the tumors showed metastatic spread. Exophytic verrucous carcinomas also occur on the penis.¹⁸¹⁹

Occasionally, explosive growth occurs after a prolonged period of slow progression. The mean duration of lesions at the time of diagnosis is 13–16 years.¹⁸²⁰ The incidence of metastasis is low; fatalities are rare but recorded.¹⁸²¹

Various factors have been implicated in the etiology of verrucous carcinomas. The chewing of tobacco or betel may predispose to oral lesions, whereas HPV has been implicated in the etiology of genitocrural lesions¹⁷⁹⁹ and, rarely, tumors at other sites.¹⁸²² HPV-6, -11, -16, and -18 have been implicated in various cases.^{1792,1823–1826} However, if the concept of **warty carcinoma** is adopted (see later), then the incidence of HPV in verrucous carcinomas will considerably decrease. A case of plantar verrucous carcinoma has been reported contiguous with a plantar wart, and this may have been of etiological significance.¹⁸²⁷ A histological pattern of lichen simplex chronicus with a variable verruciform pattern and altered epidermal differentiation has been reported on the vulva as **vulvar acanthosis**.¹⁸²⁸ The lesions were HPV⁻. The authors speculated that this lesion might be a precursor to, or a risk factor for, vulvar carcinoma.¹⁸²⁸ Trauma and chronic irritation have also been implicated in the etiology of verrucous carcinoma.¹⁸²⁹ Verrucous carcinoma needs to be distinguished from verrucous psoriasis.^{1830,1831}

Surgical excision and Mohs micrographic surgery are the treatments of choice.¹⁸⁰⁵ Some lesions are voluminous, and tumor mass reduction may be indicated before surgical excision.¹⁸³² Other therapies used include imiquimod,¹⁸³³ carbon dioxide laser, cryosurgery, radiotherapy, photodynamic therapy, and topical or systemic chemotherapy.¹⁸³² Intra-arterial infusion of methotrexate was used for a large verrucous carcinoma of the lip.¹⁸³⁴ Imaging is sometimes used to assess the extent of the lesion prior to therapy.¹⁸³⁵

Histopathology^{1799,1808,1812,1836}

Multiple biopsies are often required for the diagnosis of verrucous carcinoma. Lesions are both exophytic, with papillomatosis and a covering of hyperkeratosis and parakeratosis, and endophytic (Fig. 31.40).¹⁸¹² The rete pegs have a bulbous appearance and are composed of large well-differentiated squamous epithelial cells with a deceptively benign appearance.¹⁸³⁶ These acanthotic downgrowths sometimes extend into the deep reticular dermis and even the subcutis.¹⁸³⁷ They are blunted projections, in contrast to the uneven, sharply

Figure 31.40 Verrucous carcinoma. Well-differentiated nests of squamous epithelium extend into the dermis. (H&E)

Figure 31.41 Verrucous carcinoma. Note that the acanthotic downgrowths of epidermis are blunted; they are contained by an intact basement membrane. Also note the parakeratosis, which can extend into the epidermis to form crypts or burrows. (H&E)

pointed and jagged downgrowths seen in pseudoepitheliomatous hyperplasia.¹⁸³⁶ There is usually only very low mitotic activity, and this is confined to the basal layer (Fig. 31.41).¹⁸³⁸ The downgrowths are mostly contained by an intact basement membrane, although frankly invasive features are sometimes present. A more aggressive, cytologically malignant squamous cell carcinoma may sometimes arise in a verrucous carcinoma, either *de novo* or following X-irradiation of the lesion.¹⁸³⁹ The combination of verrucous and conventional squamous cell carcinoma is called hybrid verrucous–squamous carcinoma.¹⁸⁴⁰

Other features include the presence of burrows in the surface filled with parakeratotic horn, as well as draining sinuses containing inflammatory and keratinous debris. Keratin-filled cysts may develop within the tumor mass.¹⁸³⁶ Verruco-cystic squamous cell carcinomas appear to be more common in transplant recipients.¹⁸⁴¹ The fibrous stroma surrounding the epithelial downgrowths contains ectatic vessels and a variable inflammatory infiltrate, in which eosinophils and neutrophils are sometimes prominent.^{1808,1842} The presence of neutrophils is an important diagnostic clue. Intraepidermal abscesses are often present in lesions of long standing.

A rare entity affecting the glans penis and known as **pseudoepitheliomatous, keratotic, and micaceous balanitis** may present with the histological features of a verrucous carcinoma; in other instances, it has features of a hyperplastic dystrophy akin to vulvar dystrophy.^{1843–1845} A true verrucous carcinoma may arise within it.¹⁸⁴⁶ Its etiology is unknown; HPV infection was excluded in one case.¹⁸⁴⁷

Verrucous carcinoma should be distinguished from the exceedingly rare papillary variant of squamous cell carcinoma, which is a purely exophytic lesion, in contrast to the mixed endophytic and exophytic character of verrucous carcinoma.¹⁸⁴⁸

The concept of **warty (condylomatous) squamous cell carcinoma** has been proposed for an exophytic warty tumor of the penis (a similar lesion occurs on the vulva) usually related to HPV-16 infection.^{1849,1850} This tumor is distinguished from verrucous carcinoma on the basis of long and undulating, condylomatous papillae, with prominent fibrovascular cores and a base that is rounded or irregular and jagged. Furthermore, koilocytotic atypia is prominent and diffuse, whereas it is absent in the ‘pure’ verrucous carcinoma.¹⁸⁴⁹ Warty carcinoma of the penis appears to have a better prognosis than typical squamous cell carcinoma of the penis.¹⁸⁵¹

PCNA is expressed at the periphery of squamous nests (similar to keratoacanthomas), in contrast to the more widespread distribution in the usual type of squamous cell carcinoma.¹⁸⁵²

Differential diagnosis

The main problem in the differential diagnosis of verrucous carcinoma concerns biopsy specimens that are too shallow and do not include the entire base of the lesion. Such cases may be difficult or impossible to distinguish from verrucae, keratoacanthoma, or forms of pseudoepitheliomatous hyperplasia. Clinical history is also important for complete evaluation because lesions in characteristic locations that are of long duration or may have been previously treated as verrucae should arouse suspicion for verrucous carcinoma.

ADENOSQUAMOUS CARCINOMA

Primary adenosquamous carcinoma of the skin is a rare, usually aggressive, tumor with a potential for local recurrence and metastasis.^{1798,1853–1855}

The head and neck, and also the penis, are favored sites.^{1706,1856} Many cases in the literature have been reported as mucoepidermoid carcinomas,^{1857,1858} but this term is best reserved for morphologically related tumors arising in the salivary gland, lung, and, rarely, the skin.^{1853,1859,1860}

Both tumors are probably appendageal in origin, but because of some morphological features in common, and the presence of squamous nests, the two tumors are considered here for convenience.¹⁸⁶¹ ‘Purists’ could also argue for the removal of basal cell carcinoma from this chapter, and the ‘unitarians’ would have squamous cell carcinoma and little else in this chapter.

Histopathology^{1853,1854}

Adenosquamous carcinomas are usually deeply invasive tumors composed of islands and strands of squamous cell carcinoma admixed with glandular structures containing mucin (Fig. 31.42).¹⁸⁶² The mucin, which is of epithelial type (sialomucin), is present in the lumen and the cytoplasm of the lining cells. It stains with mucicarmine, Alcian blue at pH 2.5, and the PAS method, and it is digested by sialidase. The cells are positive for epithelial membrane antigen and cytokeratin, whereas those lining the glandular spaces stain for carcinoembryonic antigen.

Differential diagnosis

Adenosquamous carcinoma has been confused with adenoid (acantholytic) squamous cell carcinoma, but in the latter there is no mucin and the glandular spaces contain acantholytic squamous cells.¹⁸⁶³ Adenosquamous carcinoma also differs from the case reported as ‘squamous cell carcinoma with mucinous metaplasia’, which was composed of mucin-containing vacuolated cells resembling ‘signet-ring’ cells; there were no glandular spaces.¹⁸⁵³

MUCOEPIDERMOID CARCINOMA

Mucoepidermoid carcinoma is a common tumor of the salivary gland. It may also occur in other organs, such as the paranasal sinuses and lung. It is exceedingly rare in the skin.^{1859–1861,1864–1867} It has been reported in the axilla,¹⁸⁶¹ on the finger,¹⁸⁶⁵ on the scalp in a child,¹⁸⁶⁶ on the eyelid,¹⁸⁶⁷ and arising within a nevus sebaceus of Jadassohn.¹⁸⁶⁴

There is evidence that the tumor is adnexal rather than epidermal, but it is considered here for the reasons stated in the introduction to adenosquamous carcinoma.

Treatment is complete surgical excision, using Mohs technique if necessary. Local recurrences may occur after incomplete removal.¹⁸⁶⁶

Figure 31.42 Adenosquamous carcinoma. (A) There are glandular spaces containing a small amount of mucin. There are no acantholytic cells, distinguishing this lesion from an acantholytic type of squamous cell carcinoma. (H&E) (B) The cells stain with a broad keratin stain. (Keratin immunoperoxidase)

Histopathology

The lesion is often well circumscribed; it may be partly cystic. It is not attached to the epidermis. It is composed of three cell types: mucinous, squamous, and clear. The squamous cells are in lobules, and the mucigenic and clear cells are admixed. A mucin stain highlights the mucin cells, whereas all cell types express CK7, pancytokeratin, CEA, and EMA.¹⁸⁶¹ Positive p63 staining favors primary cutaneous origin over metastasis from an extracutaneous site.¹⁸⁶⁸

CARCINOSARCOMA (METAPLASTIC CARCINOMA)

Carcinosarcoma of the skin is an exceedingly rare biphasic tumor with approximately 65 cases reported to date.^{1869–1875} Biphasic sarcomatoid carcinoma is a term that is also used for carcinosarcomas, whereas monophasic sarcomatoid carcinoma has been used to describe a neoplasm composed of cytokeratin- and vimentin-positive spindle cells without a distinct carcinomatous component.¹⁸⁷⁶ Sarcomatoid carcinoma of the penis encompasses cases of biphasic and monophasic origin.^{1875,1877,1878} In one series of 15 cases, inguinal metastases were present in 89% of cases. The distinction between these various terms appears meaningless in light of their monoclonality and the likely origin of the mesenchymal component in dedifferentiated carcinomatous cells.^{1879,1880}

Carcinosarcomas are primarily tumors of the elderly, with a male sex predominance. They are located on the head in nearly 50% of cases.¹⁸⁸¹ There is a significant variation in their size.¹⁸⁷⁵ In one case, the patient had the nevroid basal cell carcinoma syndrome.¹⁸⁸² Carcinosarcoma has arisen in a nevus sebaceus; basal cell carcinoma was the epithelial component in this case.¹⁸⁸³

This tumor has metastatic potential, which is high in the case of penile lesions (discussed previously).¹⁸⁸⁴ Tumors with adnexal as opposed to epidermal components are high-risk tumors.¹⁸⁸⁵ Size greater than 4 cm is associated with a worse outcome.¹⁸⁸⁶

Complete excision of the lesion is the treatment of choice. In a recent case of carcinosarcoma with basal cell carcinoma and undifferentiated sarcoma components, both elements were found to have two identical mutations: a truncating and a missense mutation in the *PTCH1* gene.¹⁸⁸⁷ This suggests that sonic hedgehog pathway inhibitors might be useful as therapeutic agents for similar tumors.¹⁸⁸⁷

Histopathology

For this diagnosis, the tumor must contain an intimate admixture of epithelial and mesenchymal elements, both of which are malignant (Fig. 31.43).¹⁸⁷⁰ In most cases reported, the epithelial component has been a basal, adnexal, or squamous cell carcinoma,^{1869,1874,1875,1888,1889} whereas the mesenchymal component has included fibrosarcoma,¹⁸⁹⁰ chondrosarcoma, and osteogenic sarcoma¹⁸⁹¹ and sometimes other elements, such as leiomyosarcoma,¹⁸⁸⁰ angiosarcoma,¹⁸⁹² giant cell tumor of soft parts,¹⁸⁹³ or rhabdomyosarcoma.^{1874,1894} In sarcomatoid basal cell carcinomas, there appears to be a predilection for osteosarcomatous differentiation.¹⁸⁷⁹ An example of Merkel cell carcinosarcoma has been reported; the two components were Merkel cell carcinoma (positive staining for pan-cytokeratin, CK20, chromogranin, and synaptophysin) and embryonal rhabdomyosarcoma (positive staining for desmin and myogenin). Both elements were also present in the recurrence and metastasis of this tumor.¹⁸⁹⁵

Immunoperoxidase stains are of great value in elucidating the components of this tumor. Whereas the cytokeratin marker AE1/AE3 may be negative in the epithelial component, p63 and MNF116 are often expressed in poorly differentiated epithelial cells.^{1879,1896} The mesenchymal component may express vimentin, actin, CD10, CD34, and CD68, depending on its differentiation.^{1881,1890}

Figure 31.43 (A) Carcinosarcoma. (B) There is a pleomorphic sarcomatous component surrounding basosquamous epithelial nests. **(C)** Another case, showing basosquamous tumor islands and a strikingly pleomorphic, sarcomatous stromal component. (H&E)

Figure 31.44 Lymphoepithelioma-like carcinoma. Tumor cells are difficult to distinguish from the surrounding lymphoid cells. (H&E)

LYMPHOEPITHELIOMA-LIKE CARCINOMA

Lymphoepithelioma-like carcinoma of the skin is a rare tumor that resembles histologically the nasopharyngeal tumor of the same name.^{1897–1900} Approximately 50 cases have now been reported. It presents clinically as a papulonodular lesion, usually on the face or scalp.^{1901,1902} The shoulder and vulva are rare sites of involvement.¹⁹⁰³ It has arisen in the scar of a previously excised basal cell carcinoma.¹⁹⁰⁴ Metastasis is uncommon.¹⁹⁰⁵ Epstein–Barr virus (EBV) is generally not detected in tumor cells from cutaneous lesions.^{1901,1906–1908} However, examples of EBV-positive tumors have been reported from stomach, salivary gland, lung, and thymus, and recently a tumor obtained from the cheek was found to have EBV genomes by PCR and by *in situ* hybridization for Epstein–Barr virus-encoded small RNAs (EBER).¹⁹⁰⁹ HPV and simian virus 40 are also absent in this tumor.¹⁹¹⁰ Wick's group believes that this lesion is a morphological manifestation of squamous cell carcinoma.¹⁹¹¹

Histopathology¹⁸⁹⁷

The tumor may arise in the dermis or subcutis. It is composed of islands of large epithelial cells surrounded by a dense infiltrate of lymphocytes and some plasmacytoid cells (Fig. 31.44). The epithelial cells have a vesicular nucleus and a large nucleolus. There is no evidence of overt squamous differentiation, such as the formation of keratin 'pearls', intercellular bridges, or dyskeratotic cells.¹⁹¹¹ Adnexal differentiation has been reported in the epithelial nests in several cases.^{1907,1912} Another case showed spindle cell differentiation.¹⁹¹³ The overlying epidermis has been reported as normal in many cases but as dysplastic in a few.¹⁹¹⁴

The epithelial cells express cytokeratin (Fig. 31.45) and epithelial membrane antigen but not S100 protein,¹⁹⁰⁴ whereas the stromal lymphocytes express CD45 (leukocyte common antigen). Some cases have numerous factor XIIIa-positive dendritic cells in the stroma.¹⁹⁰¹

Differential diagnosis

The microscopic differential diagnosis includes lymphoma and Merkel cell carcinoma. Identification of the atypical epithelial component, together with the bland appearances of the lymphocytes and their lack of phenotypic evidence for clonality, would argue against lymphoma, although it creates an image that could be mimicked by an epithelioid T-cell lymphoma. Merkel cell carcinomas are composed of small
